Abstract: In this paper, we propose an efficient and scalable query processing framework for continuous spatial queries (range and k-nearest-neighbor queries) in mobile peer-to-peer (P2P) environments, where no fixed communication infrastructure or centralized/distributed servers are available. Due to the limitations in mobile P2P environments, for example, user mobility, limited battery power, limited communication range, and scarce communication bandwidth, it is costly to maintain the exact answer of continuous spatial queries. To this end, our framework enables the user to find an approximate answer with quality guarantees. In particular, we design two key features to adapt continuous spatial query processing to mobile P2P environments. (1) Each mobile user can specify the desired quality of services (QoS) for query answers in a personalized QoS profile. The QoS profile consists of two parameters, namely, coverage and accuracy. The coverage parameter indicates the desired level of completeness of the available information for computing an approximate answer, and the accuracy parameter indicates the desired level of accuracy of the approximate answer. (2) We design a continuous answer maintenance scheme to enable the user to collaborate with other peers to continuously maintain her query answer. With these two features in our framework, the user can obtain a query answer from her local cache if the answer satisfies her QoS requirements. Otherwise, the user enlists neighbors for help to share their cached information to refine the answer. If the refined answer still cannot satisfy the QoS requirements, the user broadcasts the query to the peers residing within the required search area of the query to find the most accurate answer. Experimental results show that our framework is efficient and scalable and provides an effective tradeoff between the communication overhead and the quality of query answers.

Keywords: Mobile computing, peer-to-peer computing, continuous query processing, spatio-temporal databases, and GIS.

1. Introduction

With the advance in new peer-to-peer (or P2P for short) wireless communication technologies, for example, IEEE 802.11 and Bluetooth, and the computational and storage capacity of portable devices, a new information access paradigm, known as mobile P2P information access, has rapidly taken shape. This paradigm is important for environments, where no fixed communication infrastructure or centralized/distributed servers are available, such as battlefield and rescue operations. It is also useful for other business and civilian applications, such as traffic monitoring and resource locator. Existing spatial query processing frameworks in mobile environments rely on fixed communication infrastructure and/or centralized servers or only support snapshot queries.

The limitations in these existing works motivate us to design a new continuous spatial query processing framework that does not require any fixed communication infrastructure or centralized/distributed servers. In particular, we focus on the two most common spatial queries, range queries and k-nearest-neighbor (k-NN) queries. Examples of these spatial queries include that the rescuers issue range queries to continuously keep track of the ambulances within a certain range in a disaster site, and the soldiers issue k-NN queries to continuously monitor their k-nearest tanks in a battlefield.

Due to the limitations in mobile P2P environments, for example, user mobility (the query issuer and the data object are continuously roaming), limited communication range, limited battery power, and scarce communication resources, it is costly to maintain the exact answer of continuous spatial queries. To this end, we propose a continuous spatial query processing framework to provide approximate answers for mobile users with quality guarantees. In particular, we design two key features to adapt continuous spatial query processing to mobile P2P environments.

[1] The user can specify the desired quality of services (QoS) for query answers in a personalized QoS profile. The QoS profile consists of two parameters, namely, coverage and accuracy. The coverage parameter indicates the desired level of completeness of the available information for computing an approximate answer, and the accuracy parameter indicates the desired level of accuracy of the approximate answer.

[2] We design a continuous answer maintenance scheme that allows the user to collaborate with peers to continuously maintain her answer, instead of always processing the query from scratch, in order to reduce communication overhead.

The main idea of our framework is that a user can obtain a query answer from her local cache if the answer satisfies...
her QoS requirements, that is, the information stored in the local cache satisfies the coverage requirement and the answer derived from the local cache satisfies the accuracy requirement. In case that the answer does not satisfy the QoS requirements, the user asks neighbors to share their cached information, in order to refine the answer. If the refined query answer still does not satisfy the QoS requirements, the user enlists the peers residing within the required search area of the query for help to find the most accurate answer, and then updates her local cache. Since the query issuer and data objects are moving, the query answer may become stale.

Thus we propose the continuous answer maintenance scheme that enables the user to collaborate with other peers to continuously maintain the query answer. When the answer derived from the local cache no longer satisfies the user's QoS requirements, the user needs to enlist peers for help to refine the answer again. We evaluate our framework through simulated experiments [5][6]. The results show that our framework is efficient and scalable in terms of communication overhead and power consumption and provides a tradeoff between the communication overhead and the quality of query answers. In this paper, we focus on continuous range and k-NN queries.

However, our framework can be extended to support other types of continuous spatial queries, if their query answers can be abstracted into monitoring regions, for example, continuous reverse-nearest-neighbor queries and continuous density queries. The rest of this paper is organized as follows. Section 2 surveys previous works related to query processing in mobile P2P environments. Our system model is presented in Section 3. Section 4 describes our continuous spatial query processing framework for both range and k-NN queries.

2. Related Work

Existing spatial query processing [5][7] frameworks in mobile environments can be categorized into four architecture approaches: centralized, semi-distributed, semi-distributed with client cooperation and wireless sensor networks.

[2] The semi-distributed approach is similar to the centralized approach, as it also relies on centralized database servers for query processing and data storage; however the servers delegate some query monitoring tasks to the mobile user in order to reduce communication overhead.

[3] The semi-distributed [9][10] with client cooperation approach considers peer collaboration in mobile P2P environments. In this approach, mobile users can only share their cached information with other peers, in which the information is previously retrieved from centralized database servers; thus, this approach does not consider query processing among the mobile users.

[4] The algorithms designed for wireless sensor networks rely on stationary sensors. Since these sensors work like distributed servers to process spatial queries, these algorithms cannot be applied to mobile P2P environments. Due to the dependency on fixed communication infrastructure and/or centralized/distributed servers, none of these techniques can be applicable to spatial query processing in mobile P2P environments. The closest works to ours are the systems that support resource discovery in mobile P2P environments. These resource discovery algorithms enable a mobile or stationary resource provider, e.g., a taxi and ATM machine, to periodically broadcast its information to mobile users, in order to look for potential customers or users.

On the other hand, a mobile user broadcasts a query to peers to express an interest in certain types of resources, e.g., Where is my nearest available taxi. Once the peer finds a match between the query and its requested resource, the peer sends the information about the available requested resource to the requesting user. Our work distinguishes itself from these works, as it

[a] Supports spatial constraints for queries, for example, the user can ask for her k-nearest resources and certain types of resources within a certain distance range.

[b] Enables the user to specify the desired QoS, namely, coverage and accuracy, for query answers, in order to achieve a tradeoff between the communication overhead and the quality of query answers, and enables the user to collaborate with peers to continuously maintain query answers, while the existing resource discovery works only consider snapshot queries.

3. System Model

We present the system model of our continuous spatial query processing framework in mobile P2P environments. Each mobile user belongs to an object type, such as taxis and police cars. A querying user issues a continuous query asking for objects of a specific type, and the peers who belong to the requested object type are referred to as the objects of interest of the query. Every mobile device is equipped with a positioning device, such as GPS [8][11], to determine its location, which is represented by a coordinate (x; y). The mobile user can communicate with all neighbors through broadcast communication, a neighbor through point-to-point communication, and a multi-hop peer through a multi-hop routing protocol which contains a sequence of point-to-point communications.

Furthermore, each user employs a neighbor discovery protocol (NDP) to maintain a list of neighbors. The basic idea of NDP is that each user periodically broadcasts a beacon message with her identity to neighbors. If the user has not received the beacon message of a neighbor for a
transmission range, therefore the peer is removed from the neighbor list. However, the user sends a message to request for the peer's information (ID, Loc, TS, MaxSpeed, and Type), where ID is the peer's identity, Loc is the peer's current location at timestamp TS, MaxSpeed is the peer's maximum mobility speed, and Type is the peer's object type, through point-to-point communication, and inserts the peer into the neighbor list.

In practice, MaxSpeed can be set to the maximum legal speed in the system area or the highest speed that has been recorded by the user for a certain time period, for example, one week. User QoS profile. Each mobile user maintains a quality of services (QoS) profile that consists of two parameters, namely, coverage (Cmin) and accuracy (Amin), where 0 ≤ Cmin; Amin ≤ 1. Cmin specifies the desired level of completeness of the available information for computing an approximate answer, and Amin specifies the desired level of accuracy of the approximate answer. The user can specify larger Cmin and Amin values to obtain an answer with better QoS, but they incur higher communication overhead. Therefore the user can tune these QoS requirements to achieve a performance trade-off between the communication overhead and the quality of query answers. The user can change her QoS requirements at any time.

spatial queries: A range query is in a form (ID, Range, Period, Loc, TS, MaxSpeed, ObjectOfInterest), where ID is the query issuer's identity, Range is the distance range of the query, Period is the valid time frame of the query, Loc is the query issuer's current location, TS is the current timestamp, MaxSpeed is the query issuer's maximum mobility speed, and ObjectOfInterest is the object type requested by the query. Given a range query, its answer includes the objects of interest residing in a rectangular query region whose left-bottom and right-top vertices are (Loc.X Range, Loc.YRange) and (Loc.X+Range, Loc.Y+Range), respectively.

A k-NN query is in a form (ID, k, Period, Loc, TS, MaxSpeed, and ObjectOfInterest), where k is the required number of objects of interest of the query and other attributes are the same as in the range query. Given a k-NN query, its answer includes the k-nearest objects of interest to Loc. Although we only focus on range and k-NN queries in this work, our framework is applicable to other continuous spatial query types [10][15] if their query answers can be abstracted into monitoring regions. For example, our framework can be extended to support reverse-nearest neighbor queries and density queries because recent research efforts have shown that the answer of these query types can be maintained by monitoring a region.

Local cache: A local cache is a user's storage space dedicated to our framework. The local cache stores three tables, area table, object table, and query table. The area table and object table maintain the received object information, while the query table maintains the received continuous queries for the continuous query answer maintenance scheme.

The details of the query table will be described in Section 4.4. Each user maintains two types of object information, neighbors and query answers. For the information of neighbors, it is modeled by a circular area as the user's transmission range [11][12], which is stored in the area table, and the object table stores the information of each neighbor, where a peer's information is in a form (ID, Loc, TS, MaxSpeed, Type), where Loc is the peer's latest location information sent by the peer at timestamp TS. For the information of a range (or k-NN) query answer, it is modeled by a rectangular (or circular) area as the query's required search area, which is stored in the area table, and the object table stores the information of the objects of interest that could reside in the required search area.

If an object is included in multiple areas in the area table, the object table only keeps one entry for the object with the latest location information received by the user through the neighbor discovery protocol, the information sharing with neighbors control flow (Section 4.2), the query broadcasting [13][14] control flow (Section 4.3), or the continuous query answer maintenance control flow (Section 4.4). Whenever the user receives the more recent location information of an object stored in the object table, the user updates the Loc and TS of the object's entry accordingly. If an object is no longer referred by any entry in the area table, the object is removed from the object table.

Figure 1 depicts the local cache of a mobile user u, where u's location is represented by a square and the peers are represented by circles with unique labels. The area table contains two areas, where the user's transmission range A1 is represented by a dotted circle with one object o4, and the required search area of a continuous range query A2 is represented by a dotted rectangle with six objects o1 to o6. Thus the object table contains one entry for each of the objects of A1 and A2, o1 to o6.

4. Query Processing Framework

Figure 2 depicts the four main control flows in our framework:
(1) QoS measurements for a local cache
(2) Information sharing with neighbors
(3) Query broadcasting and
(4) Continuous query answer maintenance.

Algorithm 1 outlines the first three control flows and Algorithm 2 outlines the fourth control flow. We will describe each control flow in detail.
4.1 QoS Measurements for a Local Cache

This is the first control flow in our framework, which is indicated by thin lines in Figure 2 (Lines 2 to 7 in Algorithm 1). This control flow is completely executed on the mobile user side without enlisting peers for help. Due to user mobility, the cached peer location information could become stale. To capture location uncertainty, we employ a conservative approach that models an uncertain location as an adjusted location region. The adjusted location region of a peer's location \cite{17}\cite{18} is a circular region centered at the peer's location with a radius of \((t_{\text{current\ TS}}) \cdot \text{MaxSpeed})\), where \(t_{\text{current}}\) is the current time and TS is the timestamp of the latest location update.

In other words, the peer can move in any direction at the maximum mobility speed MaxSpeed. We will present how to determine the coverage and accuracy for a query with respect to the information stored in a local cache for both range queries and k-nearest-neighbor (k-NN) queries.

4.1.1 Coverage Measurement

The coverage measurement \cite{11}\cite{15} indicates the level of completeness of the available information in a local cache for computing a query answer. Given the required search area of a query and a local cache, the coverage of the information in the local cache is measured by the ratio of the intersection of the required search area and the union of the areas stored in the area table to the required search area. Formally, given a required search area \(S\) and a set of \(n\) areas \(A_1, A_2, \ldots, A_n\) in the area table in a local cache \(L\), the coverage of \(L\) with respect to \(S\) is calculated as:

\[
Cov(S, L) = \frac{\text{Area}(S \cap (A_1 \cup \ldots \cup A_n))}{\text{Area}(S)}
\]

where \(\text{Area}(R)\) is the area of a region \(R\).

Since calculating the exact coverage of a large number of overlapping areas is costly, we use a histogram approach to get approximate coverage measurement. The basic idea is that we model the required search area by a uniform grid structure and maintain a bitmap, in which each bit corresponds to a unique grid cell. Initially, all bits in the bitmap are set to zero. For each grid cell, if it is totally covered by some area stored in the area table, the corresponding bit is set to one. The coverage is the number of one in the bitmap divided by the total number of bits in the bitmap. Since the bit of a grid cell is set to one if its area is totally covered by some monitored area, a larger grid cell area results in a larger underestimation of the coverage measurement. Although a smaller grid cell area gives higher computation precision, it incurs higher computational overhead.

In Section 6.3, we study this performance tradeoff between the computational overhead and the coverage measurement precision. We will discuss the coverage measurement for range and k-NN queries. Range queries. Figure 3a shows a user's local cache, which stores the information about the user's neighbors (the area of the user's transmission range is represented by a dotted circle) and the adjusted required search area of the user's continuous range query is represented by a dotted rectangle. The detail of how to adjust the required search area of a continuous range query will be discussed in Section 4.4.

In this example, the user wants to measure the coverage of the information stored in the local cache with respect to the same continuous range query, where the user's location is represented by a filled square, the query region1 of the range query is represented by a rectangle, and the adjusted location region of each object stored in the object table is represented by a circle with a unique label. Since the required search area of a range query is the same as its query region, the user can calculate the coverage without enlisting any peers for help. In Figure 3b, we assume that the required search area is modeled by a uniform grid structure of 10 cells. Since all grid cells, which are represented by shaded cells, are totally covered by the areas stored in the area table, A1 and/or A2, all bits in the bitmap are set to one; hence the coverage is 100/100 = 1. k-NN queries.
where the local cache stores the information about the user’s neighbors (the area of the user’s transmission range is represented by a dotted circle) and the adjusted required search area of the user’s outstanding continuous range query is represented by a dotted rectangle. In this example, a user wants to measure the coverage of the information stored in the local cache with respect to a new k-NN query. The required search area of a k-NN query is a minimal circle that totally covers the exact location or the adjusted location region of k objects of interest. These k objects are not necessary to be the k-nearest objects to the user. However, if the user cannot find at least k objects of interest in the local cache, the user is unable to determine the required search area of the query, \( S = \emptyset \). Thus the user cannot perform the coverage measurement, and the user proceeds to the next control flow: information sharing with neighbors.

In this example, we assume that all objects \( o_1 \) to \( o_6 \) are the objects of interest of the query; therefore the required search area of the query is a circle (represented by a bold circle) that totally covers the adjusted location regions of 3-nearest objects, \( o_2, o_4, \) and \( o_6 \). Then we construct a minimum bounding rectangle of the required search area and model the rectangle by a uniform grid structure of 10 \( \times \) 10 grid cells, as depicted in Figure 4b. Since 72 grid cells, which are represented by shaded cells, are totally covered by the areas, there are 72 bits in the bitmap are set to one; hence the coverage is \( 72/100 = 0.72 \).

4.1.2 Accuracy Measurement

The accuracy measurement indicates the level of accuracy of an approximate answer, which is derived from a local cache. It is important to note that we only determine an approximate query answer if the coverage requirement is satisfied. Since it is very costly to determine an exact probabilistic answer for a k-NN query, even an approximate approach is computationally expensive [25], these approaches are not suitable for mobile devices with limited computational resources. To this end, we use a heuristic approach to measure the accuracy of a range or k-NN query answer.

The accuracy measurement is defined as follows: Given a query with a required search area \( S \), a set of \( m \) objects of interest of the query whose exact locations or adjusted location regions intersect \( S \), \( O = \{o_1; o_2\} \), the probability \( p_i \) of each object \( o_i \in O \) being part of the query answer, where \( p_i \geq 0 \), and an approximate answer \( A = \{a_1; a_2; \ldots; a_n\} \), ong, where \( A \subseteq O \), the accuracy, \( Acc(O; A) \), is computed as the average of (a) the probability \( p_i \) of correctly making a decision of including an object \( o_i \in A \), and (b) the probability \( 1 - p_i \) of correctly making a decision of excluding an object \( o_i \notin A \); hence the accuracy of \( A \) is computed as:

\[
Acc(O, A) = \frac{1}{m} \left[ \sum_{o_i \in A} p_i + \sum_{o_i \in O - A} (1 - p_i) \right]
\]

We assume a uniform distribution for the actual location of an object \( o_i \) in its adjusted location region when computing \( p_i \) for both range and k-NN queries; however our algorithm is completely independent of how we compute \( p_i \). The following theorem shows the correctness of Equation 2. Range queries.

Figure 5a shows a range query, where its query region is represented by a rectangle and the adjusted location region of each object of interest of the query that intersects the query region is represented by a circle. Since the required search area of a range query is the same as its query region, \( O \) contains the objects of interest of the query whose exact locations or adjusted location regions intersect the query region; thus \( O = \{o_1; o_2; o_3; o_4; o_6\} \). For each object \( o_i \in O \) with an exact location, \( p_i \) is set to one because \( o_i \) must reside in the query region. On the other hand, for each object \( o_i \in O \) with an adjusted location region, since we consider a uniform distribution, \( p_i \) is computed as the ratio of the area of the intersection of the adjusted location region and the query region to the area of the adjusted location region.

---

**Fig. 5:** Accuracy measurement.

We can maximize the accuracy of an approximate range query answer by maximizing \( p_i \) in each term in \( Acc(O; A) \). Thus if \( p_i \geq 0.5 \), \( o_i \) should be included in \( A \); however if \( p_i < 0.5 \), \( o_i \) should be excluded from \( A \). The correctness of this selection threshold is proved in Theorem 2. The accuracy measurement for k-NN queries has two steps.

Step 1: Distance threshold step. We already find the required search area of a k-NN query during the coverage measurement. We consider the objects of interest of the query \( O = \{o_1; o_2\} \); whose exact locations or adjusted location regions intersect the required search area. For each object \( o_i \in O \) with an adjusted location region, we determine a distance range \([d_{\text{mini}}; d_{\text{maxi}}]\), where \( d_{\text{mini}} \) and \( d_{\text{maxi}} \) are the smallest and largest possible distances between \( o_i \) and the querying user \( u \), respectively. On the other hand, for each object \( o_i \in O \) with an exact location, both \( d_{\text{mini}} \) and \( d_{\text{maxi}} \) are set to the distance between \( o_i \) and \( u \).

Then the objects in \( O \) are sorted by their smallest possible distances in increasing order. We find the smallest possible distance of the \((k+1)\)-st object in the sorted \( O \) as a minimum threshold distance, \( T_{\text{mini}} \), and the largest possible distance of the \( k \)-th object in the sorted \( O \) as a maximum threshold distance, \( T_{\text{maxi}} \). Figure 5b shows the...
sorted $O = \{o_4; o_2; o_6; o_1; o_3; o_5\}$, where the smallest and largest possible distances of the adjusted location region of each object to $u$ are represented by $t$ and $u$, respectively. Since $o_1$ is the $(k+1)$st object, $T_{min} = d_{min1}$ that is represented by a dotted line. Since $o_6$ is the $k$th object, $T_{max} = d_{max6}$ that is represented by a line.

Step 2: Answer selection step. We select the $k$ objects with the smallest minimum possible distance to an answer set $A$.

**Algorithm 1 Continuous spatial query processing**

1: function PROCESSING (Query $Q$, LocalCache $L$, Float $C_{min}$, $A_{min}$)

// Control Flow 1: QoS measurements for a local cache
2: $S$ the required search area of $Q$
3: if $S \neq \text{null}$ and $\text{cov}(S,L) \leq C_{min}$ then
4: $O$ the objects of interest of $Q$ in $L$ intersecting $S$
5: $A$ an answer derived from $O$
6: if $\text{Acc}(O;A) \leq A_{min}$ then return $A$
7: end if
// Control Flow 2: Information sharing with neighbors
8: $L_p$ the neighbor's transmission range and the monitored area of the query whose requested object type is the same as $Q$, and their objects
9: $S$ the required search area of $Q$
10: if $S \neq \text{null}$ and $\text{cov}(S,L, \{L_p\}) \leq C_{min}$ then
11: $O$ the objects of interest of $Q$ in $L$ intersecting $S$
12: $A$ an answer derived from $O$
13: if $\text{Acc}(O;A) \leq A_{min}$ then return $A$
14: end if
// Control Flow 3: Query broadcasting
15: $S$ the required search area of $Q$
16: Find the objects of interest residing in $S$
17: Update the area table and object table accordingly
18: Compute a query answer $A$
19: return $A$

These selected objects are the first $k$ objects in the sorted $O$ and their minimum possible distances are less than $T_{max}$. For each object $oi \in A$, $p_i = \min(T_{min} - d_{min} - d_{max} + d_{mni})$ because if the actual distance between $oi$ and $u$ is equal to or less than $T_{min}$, $oi$ must be one of the $k$-NN to $u$. Thus the probability of correctly making a decision of including $oi$ in $A$ is $p_i$. For each object $oj \neq a$, $p_j = (T_{max} - d_{mni})/(d_{max} - d_{mni})$ because if the actual distance between $oj$ and $u$ is equal to or less than $T_{max}$, $oj$ could be one of the $k$-NN to $u$. Thus the probability of correctly making a decision of excluding $oj$ from $A$ is $1 - p_j$.

Figure 5b shows the sorted $O = \{o_4; o_2; o_6; o_1; o_3; o_5\}$ of a $3$-NN query. The first three objects, $o_4$, $o_2$, and $o_6$, are selected to an answer set $A$. Each object $oi \neq a$ must be one of the $k$-NN to $u$ if the actual distance between $oi$ and the querying user $u$ is within a distance range $\min(T_{min} - d_{min} + d_{max} - d_{mni})$, which is represented by a gray bold line. We assume $p_4 = 1$, $p_2 = 0.3$, and $p_6 = 0.2$. For each object $oj \neq a$, $o_1$, $o_3$, and $o_5$, $oj$ could be one of the $k$-NN to $u$, if the actual distance between $oj$ and $u$ is within a distance range $T_{max} - d_{minj}$, which is also represented by a gray bold line.

After the user submits a query and QoS profile to the continuous query processor, which is indicated by the flow labeled by $1a$ in Figure 2, if the continuous query processor finds an approximate answer that satisfies the user's coverage and accuracy requirements, it returns the answer to the user (this flow is labeled by $1b$). Otherwise, the continuous query processor proceeds to the next control flow, that is, information sharing with neighbors (this flow is labeled by $2a$).

### 4.2 Information Sharing with Neighbors

This is the second control flow in our framework, which is indicated by thick lines in Figure 2 (Lines 8 to 14 in Algorithm 1). When a querying user $u$ fails to get an answer from the local cache, the continuous query processor initiates this control flow. Since this control flow is very simple, we only present its main idea for both range and $k$-NN queries, which can be summarized into two steps.

Step 1: Information sharing step. In this step, $u$ sends the query to the neighbors through broadcast communication. Each neighbor $p$ replies to $u$ with (1) the area of $p$'s transmission range along with its objects that belong to the requested object type of $u$'s query; and/or (2) the monitored required search area of each $p$'s continuous query along with its monitored objects if its requested object type is the same as $u$'s query, through point-to-point communication.

Step 2: Answer refinement step. After $u$ receives the information from her neighbors, $u$ updates the location information of the objects stored in the object table accordingly (this flow is labeled by $2b$ in Figure 2). If the coverage of the information stored in $u$'s local cache and the information returned by the neighbors with respect to the query satisfies $u$'s coverage requirement, $u$ derives a new answer from the local cache. If the answer also satisfies $u$'s accuracy requirement, the continuous query processor returns the answer to $u$ (this flow is labeled by $2c$). If the answer still cannot satisfy $u$'s QoS requirements, the query processor proceeds to the query broadcasting control [19][20] flow (this flow is labeled by $3a$).

### 4.3 Query Broadcasting

This is the third control flow in our framework, which is indicated by very thick lines in Figure 2 (Lines 15 to 19 in Algorithm 1). The key functions of this control flow are to 1. Search the objects of interest of a query residing in its required search area in order to find the most accurate answer; and 2. Have an opportunity for a peer to update an object's location stored in the local cache when the peer is involved in routing messages [18][21] for query processing, which contains the more updated location of the object. The latter function is useful to reduce the
location uncertainty of the objects stored in the local cache.

Figures 6a and 6b illustrate this control flow for range and k-NN queries, respectively. In both examples, there are 20 mobile users, m1 to m20, where m15 is a querying user (represented by a square), the objects of interest of the query are m6, m7, m16, m18, and m20, which are represented by triangles, and other users are represented by circles. A user's transmission range is represented by a dotted circle. Since this control flow will provide the most accurate answer for a query, the relevant information of this query is removed from the query table and the object table before initiating this control flow. In general, the query broadcasting control flow has two main steps.

4.3.1 Required search area step

We will discuss how to find the required search area of a range or k-NN query. Range series. Since the required search area of a range query is the same as its query region, the querying user u can determine the required search area without enlisting peers for help. In Figure 6a, the required search area of the range query is represented by a rectangle. k-NN queries. For a k-NN query, the querying user u needs to broadcast the query to peers to find at least k objects. Then the required search area of the query is a circular area centered at u with a radius of the required search range of the query, which is the distance from u to the k-th nearest object. To find at least k objects, u broadcasts the query with a hop distance h = 1 to the neighbors. If u cannot find at least k objects within one hop, u increases h by one and rebroadcasts the query with the updated h to the neighbors.

When a peer p receives the query, p sends its information to u through point-to-point communication. If the received h is larger than one, p decreases h by one and forwards the query with the updated h to the neighbors through broadcast communication. p simply drops duplicate messages without processing or forwarding them. It is important to note that when a peer participates in routing a reply to u, the peer has an opportunity to update the location information of the objects stored in the local cache. U keeps performing this broadcast process until u finds at least k objects of interest. It is expected that u receives replies from more peers as h increases. Receiving the replies from the same set of peers with two consecutive hop distances, h and h+1, implies that the total number of objects of interest of u's query in u's network partition or the system is less than k.

When this case takes place, u can postpone this step for a while or proceed to the next step by reducing k to the number of objects of interest that are already found by this step. In Figure 6b, the querying user u = m15 issues a 3-NN query. After u broadcasts the query with a hop distance h = 1 to the neighbors, u receives replies from three peers, m12, m16, and m18, which are located in u's transmission range [22] (represented by a black dotted circle).

Among these three peers, u finds two objects of interest, m16 and m18. Since u requires three objects to determine a required search area, u rebroadcasts the query with an increased hop distance h = 2. Then u receives replies from five more peers, m2, m6, m11, m13, and m17, which are located in the transmission ranges of m12, m16, and m18 (represented by gray dotted circles). Since u finds three objects of interest, m6, m16, and m18, u terminates the broadcast process and determines the required search area. The required search area is a circle centered at u with a radius of the required search range, which is the distance from u to the 3-th nearest object, m6, which is represented by a black circle. Although u already finds three objects of interest, they do not constitute a correct query answer. This is because the correct answer is m16, m18 and, m7. This missing of m7, which is outside the searched area with h = 2, will be resolved in the next step.

Algorithm 2 Continuous query answer maintenance

4: 2: if Q is a k-NN query then
5: 3: Send Q and AggregateMaxSpeed to the peers residing in S
6: 4: end if
7: 5: Update the object table when receiving a notification message
8: 6: Periodically evaluate the query answer A
9: 7: if A becomes uncertain and Acc(A) < Amin then
10: 8: Go to Line 2 in Algorithm 1 to start the Control Flow 1
11: 9: else return A

4.3.2 Query dissemination step

Once we finish the required search area step, both range and k-NN queries are boiled down to range queries with their required search areas as the range query region. The main idea of this step to retrieve the objects of interest within the range query region u broadcasts the query along with the range query region to the neighbors. When a peer p receives the query, if p belongs to the requested object type, p sends its information to u through point-to-point communication. In addition, if p's transmission range intersects the range query region, p rebroadcasts the query to the neighbors. Similar to the required search area step, the peer participating in routing messages [23] has an opportunity to update the peer location information stored in the local cache. After u receives the replies from the objects of interest within the range query region, u computes the answer.
Range queries: The answer of a range query simply includes the objects of interest located in the required search area. Figure 6a shows that u receives replies from four objects of interest, m6, m7, m16, and m18, and these objects constitute the query answer.

k-NN queries: Among the objects of interest located in the required search area of the query, u selects the k-nearest objects as the answer. Figure 6b shows that u receives replies from four objects of interest, m6, m7, m16, and m18. After the continuous query processor [24] finds the query answer, it updates the local cache accordingly (this flow is labeled by 3b). The required search space of the query along with the ID list of its objects of interest residing in the required search area is inserted into the area table. Then the information of these objects is inserted into the object table. Finally the answer is returned to the user (this flow is labeled by 3c). We will describe how to monitor the answer in the continuous query answer maintenance control flow.

4.4 Continuous Query Answer Maintenance
This is the fourth control flow in our framework, which is indicated by a very thick white line in Figure 2 and outlined by Algorithm 2. The main tasks of this control flow are (1) collaborative query maintenance: the querying user collaborates with peers to forward the query to other peers who could become part of the answer (Section 4.4.1); and (2) query evaluation: the querying user computes the answer locally as long as the answer derived from the local cache satisfies her QoS requirements (Section 4.4.2).

4.4.1 Collaborative query maintenance
Each user maintains a query table. In the query table, a range query is stored in a form (ID, Loc, TS, Range, Period, MaxSpeed, ObjectOfInterest), where ID is the query issuer's identity, Loc is the query location point, TS records the time when the query is issued, Range is the required search range of the query, Period is the valid time period of the query, MaxSpeed is the maximum mobility speed of the query issuer, and ObjectOfInterest is the requested object type of the query. Likewise, a k-NN query is stored in a similar form (ID, Loc, TS, Range, Period, MaxSpeed, ObjectOfInterest, and AggregateMaxSpeed), where AggregateMaxSpeed is the maximum mobility speed of the objects of interest that could reside in the required search area of the query. In general, the collaborative query maintenance task has three main steps.

Step 1: Query dissemination step.
This step mainly disseminates a query to the peer located in the required search area. For a range query, since its required search area is the same as its query region, the peer can store the query in the query table during the query dissemination step in the query broadcasting control flow, as discussed in Section 4.3. On the other hand, for a k-NN query, it needs to disseminate an extra parameter for the query, AggregateMaxSpeed, to the peer located in its required search area. Thus after the querying user u gets a query answer, u broadcasts the query and its AggregateMaxSpeed to the peer residing in the required search area. Then the peer stores the query in the query table.

Step 2: Query table synchronization step.
When a peer p discovers a new neighbor p0, this step takes place to synchronize the query tables of p and p0 through a three-way message exchange via point-to-point communication. Without loss of generality, we assume that the peer with a smaller ID initiates this step. We consider that p initiates this step. (1) p sends a list p:L of the query IDs in the query table to p0. (2) After p0 receives p:L, p0 generates a list p0:L of the query IDs in the query table. Then p0 replies to p with the information of the queries in p0:L but not in p:L, p0:L\ p:L, and a list of query IDs in p:L but not in p0:L, p:Ln0:L. (3) p stores the received queries in the query table and sends the information of the queries included in the received list to p0. p0 stores the received queries in the query table.

Step 3: Notification step.
For each new query received during the query table synchronization step, the peer, p and/or p0, performs this step to decide whether to send its information to the query issuer. Due to user mobility, the peer has to adjust the required search area of a range or k-NN query to capture the effect of location uncertainty. We will discuss how to adjust the required search area of a range or k-NN query. Range queries. Figure 7a shows a range query, where the original query location point is represented by a gray square and the original required search area is represented by a dotted rectangle. Similar to the location adjustment of peer locations,

We use a conservative approach to adjust the required search area of the range query, where the querying user u can move at the maximum mobility speed MaxSpeedu in any direction. Thus the distance from the original query location point and the u's current location is at most \( r = (t\text{current} - TS) \cdot \text{MaxSpeed}_u \). In other words, u could be anywhere within a circular location region centered at the original query location point with a radius of \( r \), which is represented by a gray circle. To ensure that an adjusted required search area contains all the possible range query
regions, regardless of the u's actual location within u's adjusted location region, we extend each edge of the original required search area by r. The adjusted required search area is represented by a rectangle.

**k-NN queries:** Figure 7b shows a k-NN query, where the original query location point is represented by a gray square and the original required search area is represented by a dotted circle. Similar to range queries, the adjusted location region of a querying user u is centered at the original query location point with a radius of \( r = (\text{current} - \text{TS}) \cdot \text{MaxSpeed}_u \), which is represented by a gray circle. Consider a case that all the objects of interest residing in the required search area move at AggregateMaxSpeed; therefore the maximum possible distance between u and each of these objects is \( r \cdot \text{max}_{\text{Range}} \), where \( \text{max} = \text{AggregateMaxSpeed} \), and Range is the original required search range, which is the original distance between u and the k-th nearest object in the answer. Since u could be anywhere within the adjusted location region, the adjusted required search area is a circular area centered at the original query location point with a radius of \( 2 \cdot r \cdot \text{max}_{\text{Range}} \). Whenever u finds a larger AggregateMaxSpeed, u broadcasts it to the objects residing in the adjusted required search area. After the peer, p and/or p0, determines the required search area of a newly received query, if the peer is located in the adjusted required search area, the peer sends her information as a notification message to the querying user through point to point communication. Otherwise, the peer will periodically evaluate the query until the query is expired.

### 4.4.2 Query evaluation

The main idea of this task is that the querying user, u, checks whether to derive a certain query answer from the local cache. A certain query answer can be returned to u without any QoS measurement. If u cannot get a certain answer from the local cache, u can find an answer from the local cache as long as the answer satisfies her QoS requirements.

![Fig. 8: The answer of a 3-NN query.](image)

In case that u cannot find an answer from that satisfies her QoS requirements, u re-starts the query processing by executing the second control flow: information sharing with neighbors. Once u receives a notification message through the collaborative query maintenance task, u updates the object table accordingly. It is important to note that u will adjust the required search area of the queries stored in the area table as in Section 4.4.1, when u is requested to return the information of the local cache to a peer in the information sharing step in the second control flow.

We will describe how to check the certainty of a range or k-NN query answer. Range queries. Since the required search area of a range query is the same as its query region, the querying user u always knows the exact required search area of the query. Thus u simply adjusts the location of the objects of interest stored in the local cache, and then selects the objects with adjusted location regions intersecting the query region. If all these objects are totally included in the required search area, the accuracy of an answer that includes all these objects is one; hence this answer is a certain one.

**k-NN queries:** In contrast to range queries, u needs to determine the required search area of a k-NN query, and calculate the minimum and maximum possible distances between each object of interest in the local cache to u's current location. Then u finds an object p with the k-th smallest maximum possible distance. The required search area is a circle centered as u's current location with a radius of the maximum distance between p and u. If there are only k objects intersecting the required search area, their adjusted locations or exact locations must be totally included in the required search area; therefore these k objects constitute a certain query answer.

Figure 8 shows the answer of a 3-NN query at two time instances, where the current location of the querying user u is represented by a black square, and the exact location or the adjusted location region of each object of interest of the query is represented by a black circle or a dotted circle, respectively.

Figure 8a shows an answer, in which o5 has the third smallest maximum possible distance to u; therefore the required search area (represented by a circle) is a circular area with a radius of the distance from u to the farthest point on the adjusted location region of o5 from u. Since there are only three objects, o2, o4, and o5, whose adjusted location regions are totally covered by the adjusted required search area, these objects constitute a certain answer.

Figure 8b shows the query answer at a later time, where the adjusted location regions of objects, o1 to o5, are expanded, and the location of o6 is adjusted. o5 still has the third smallest maximum possible distance to u, so the required search area is a circle at u with a radius of the distance from u to the farthest point on the adjusted location region of o5. Since the adjusted location regions of four objects, o2, o3, o4, and o5, intersect the required search area, any three of these four objects could be the actual query answer; hence the answer becomes uncertain, and u needs to check the accuracy of the query answer.

### 5. Simulation Model

In this section, we present a simulation model [25][26] that is used to evaluate our continuous spatial query
processing framework (denoted as ContQP) in a mobile P2P environment.

5.1 Baseline Algorithms
To our best knowledge, ContQP is the first framework realizing continuous spatial query processing in mobile P2P environments. We design two baseline algorithms that have a subset of the control flows of ContQP to evaluate the performance of ContQP. Since the continuous query answer maintenance scheme (the fourth control flow) is one of the key features of our framework, the baseline algorithms do not have this control flow.

1. In the first baseline algorithm (denoted as LocalQP), the user only monitors the transmission range. If the user cannot find an answer that satisfies her QoS requirements from the local cache, that is, the first control flow: QoS measurements for the local cache, the user executes the query broadcasting control flow (the third control flow) to find the answer.

In the second baseline algorithm (denoted as PeerQP), if the user fails to find an answer from a local cache, the user proceeds to the information sharing with neighbors (the second control flow) to find the answer. If the answer still cannot satisfy the user’s QoS requirements, the user executes the query broadcasting control flow to find the answer.

5.2 Power Consumption Model
Each mobile user is equipped a wireless network interface card that supports two communication methods: point-to-point and broadcast communication. The user can communicate with all neighbors through broadcast communication, one of the neighbors through point-to-point communication, and a multi-hop peer through a point-to-point multi-hop routing that contains a sequence of point-to-point communication.

In this work, we focus on the application layer and do not have any assumption on the underlying multi-hop routing protocol; therefore any multi-hop routing protocol can be applied to our framework. It has shown that the power consumption of wireless communication can be modeled by linear formulas in terms of message sizes and communication methods. For point-to-point communication, \( P_{point} \), a source user \( S \) sends a message to a destination user \( D \). The affected users of this communication method are the users who reside in \( S \)'s transmission range, \( \text{RS} \), \( D \)'s transmission range, \( \text{RD} \), and their transmission ranges, \( \text{RSD} \). The power consumption of \( P_{point} \) is measured by the following equations.

\[
P_{point} = \begin{cases} (v_{send} \times |msg|) + f_{send}, & \text{for } S \\ (v_{recv} \times |msg|) + f_{recv}, & \text{for } D \\ (v_{ad-disc} \times |msg|) + f_{ad-disc}, & \text{for peers } \in \text{RS} \\ (v_{sd-disc} \times |msg|) + f_{sd-disc}, & \text{for peers } \in \text{RD} \\ (v_{s-disc} \times |msg|) + f_{s-disc}, & \text{for peers } \in \text{RS} \\ (v_{d-disc} \times |msg|) + f_{d-disc}, & \text{for peers } \in \text{RD} \end{cases}
\]

For broadcast communication, \( P_{bc} \), a source user \( S \) broadcasts a message to the peers residing in \( S \)'s transmission range, \( \text{SR} \). The power consumption of \( P_{bc} \) is measured by the following equations: The parameter settings for \( P_{point} \) and \( P_{bc} \) are depicted in Tables 1 and 2, respectively.

\[
P_{bc} = \begin{cases} (v_{bsend} \times |msg|) + f_{bsend}, & \text{for } S \\ (v_{brecv} \times |msg|) + f_{brecv}, & \text{for peers } \in \text{RS} \end{cases}
\]

5.3 Performance Metrics
We evaluate the performance of our framework in terms of four metrics.
1. Number of messages: metric measures the average number of messages incurred by our framework per query evaluation.
2. Power consumption: metric measures the average power consumption per query evaluation based on the power consumption models described in Section 5.2.
3. False negative: This metric measure the average relative number of objects missed in an approximate answer compared to an actual one. Given an actual answer set \( A \) and an approximate answer set \( bA \), the relative false negative is computed as \( jA \cap bA = jA \).
4. False positive: This metric measure the average relative number of extra objects in an approximate answer compared to an actual one. The false positive is computed as \( j bA \cap A \).

5.4 Simulation Settings
We implement our framework for both range queries continuously report the object(s) of a specific type within a certain range from a query issuer, and k-NN queries continuously report the k-nearest object(s) of a specific type.
type to a query issuer in C++. Each experiment runs 1,000 seconds. Unless mentioned otherwise, we generate 200 mobile users moving at a speed distributed uniformly between 1 and 20 meter(s) per second based on the random waypoint model [27] in a 1,000m × 1,000m space. Each user belongs to one of 10 object types. 20% of the users issue continuous queries for a time period of 1,000 seconds, and they evaluate their query answers every second.

<table>
<thead>
<tr>
<th>Parameters</th>
<th>Default Values</th>
<th>Ranges</th>
</tr>
</thead>
<tbody>
<tr>
<td>No. of mobile users</td>
<td>200</td>
<td>100 to 500</td>
</tr>
<tr>

<tr>
<td>No. of object types</td>
<td>10</td>
<td>-</td>
</tr>
</tbody>
</table>

The default coverage, Cmin, and accuracy, Amin, requirements are set to 0.8. The grid cell area for the approximate coverage measurement is 16 m². The transmission range of each user is 100 meters, and the beacon interval is one second. We first assume that a querying user receives the beacon her neighbors before evaluating a query, and then we remove this assumption by increasing the beacon interval in Section 6.6.

For query parameters, the range distance, Range, of range queries is 200 meters, and the required number of objects, k, of k-NN queries is five. Table 3 summarizes the parameter settings.

6. Experimental Results

This section presents the experimental results of our framework, ContQP, in comparison with the baseline algorithms, LocalQP and PeerQP, with respect to various numbers of users, numbers of continuous queries, QoS requirements, query parameters (the range distance of range queries and the value of k of k-NN queries), user mobility speeds, beacon intervals, and query period intervals.

6.1 Effect of the Number of Users

Figures 9a and 9b show that ContQP outperforms the baseline algorithms in terms of number communication overhead. The reason is that LocalQP executes the query broadcasting control flow for each query evaluation and PeerQP only slightly reduces the number of times of executing this control flow. On the other hand, ContQP effectively avoids executing the relatively expensive query broadcasting control flow through the continuous query answer maintenance control flow that efficiently maintains the user's local cache. Increasing the number of users results in more users residing in the required search area of queries, thus the communication overhead increases.

Figure 9c shows that the false negative improves, as there are more users. In a sparser environment [18] [26], the user is more likely to suffer from a network partition problem, in which the user is unable to communicate with all objects residing in the query's required search area. With a higher user density, the user has a lower probability of suffering from the network partition problem, so the false negative reduces. When there are more users, ContQP has a higher probability to select more extra objects to an answer (Figure 9d). Since the false positive of ContQP for range queries in all the experiments is user of ContQP has a higher probability to get an answer from the information shared by neighbors about the adjusted research search area of their queries and their transmission ranges.

Since PeerQP does not continuously maintain the query answer, the user only as a higher chance to get the query answer from the information shared by neighbors about their transmission ranges; thus PeerQP slightly reduces the power consumption. The number of querying users has only slight effect on the false negative (Figure 11b). Figure 12 shows that the results of k-NN queries are similar to that of range queries.
6.2 Effect of QoS Requirements

Table 4 shows the precision of the approximate coverage measurement with respect to increasing the grid cell area from 22 to 122 m². Since, the bit of a grid cell is set to one, if it is totally covered by some monitored area that is either stored in a user's local cache or shared by a user's neighbor, increasing the grid cell area leads to a larger underestimation of the approximate coverage measurement. The results indicate that when the grid cell area increases, the precision only degrades slightly, while the computational time significantly decreases. Therefore, we choose 16 m² as the default grid cell area [22][24] for all the experiments because this area size gives the greatest improvement ratio on the computational time.

Figures 13 and 14 show that the coverage requirement, Cmin, only affects ContQP slightly for range and k-NN queries, respectively. After ContQP finds a query answer, the query's required search area is contained by the adjusted required search area that is monitored by the continuous query answer maintenance control flow, the coverage of the information stored in the local cache with respect to the query is one. Figure 13a shows that PeerQP incurs less communication overhead than ContQP, as Cmin is small. This is because the user of PeerQP is more likely to find an answer from the local cache or the information shared by neighbors; however, the query answer accuracy is very low (Figure 13b).

Figures 15 and 16 show that when the accuracy requirement, Amin, gets larger, the communication overhead of ContQP increases, while its accuracy improves. This is because a larger Amin results in a higher probability that the user needs to execute the relatively expensive query broadcasting control flow to find the most accurate possible query answer. However, LocalQP executes this control flow for each query evaluation, while PeerQP has a much higher chance to execute this control flow than ContQP. Therefore, Amin achieves a tradeoff between the communication overhead and the query answer accuracy for ContQP.

6.3 Effect of Query Parameters

Figure 17 shows the results of all the algorithms with respect to increasing the range distance, Range, of range queries from 150 to 350 meters. It is expected that the communication overhead increases, as Range gets larger (Figure 17a). ContQP is more scalable than the baseline algorithms, because ContQP has a higher probability to find an answer from the information shared by neighbors, when Range increases. The increase of Range results in larger required search areas for queries, where the user is more likely to suffer from the network partition problem; thus the false negative increases (Figure 13b).

Figure 18 shows the performance of all the algorithms with respect to increasing the required number of objects of interest, k, of k-NN queries from 2 to 10. Similar to range queries, increasing k incurs higher power consumption and ContQP is more scalable than the baseline algorithms (Figure 18a). When k is larger, there is a higher probability for the user of ContQP and PeerQP to execute the query broadcasting control flow to find the most accurate possible answer; thus their query answer accuracy improves (Figure 18b).
6.4 Effect of Mobility Speeds

Figures 19 and 20 show the performance evaluation with respect to varying the user mobility speed from [1; 5] to [1; 30] meters per second for range and k-NN queries, respectively. Since LocalQP executes the query broadcasting control flow for each query evaluation, it is not affected by the mobility speed. PeerQP is only slightly affected by the mobility speed, as it only avoids a small number of times of executing the query broadcasting control flow. When the mobility speed increases, ContQP incurs higher power consumption (Figures 19a and 20a). The reason is that increasing the mobility speed results in higher uncertainty in location information, which leads to a higher decay rate in the accuracy of an answer derived from a local cache; thus ContQP has a higher probability to execute the relatively expensive query broadcasting control flow to find the answer. Since the user can get most cases, so its performance is slightly affected by the query period. However, the communication overhead of ContQP reduces and then stabilizes, as the query period increases (Figure 22a). In the experiment, we maintain the same number of querying users, decreasing the query period results in more new querying users that execute the relatively expensive query broadcasting control flow to find initial query answers. Figure 22b shows that the answer accuracy reduces, as the query period increases. This is because the uncertainty of the location information stored in a user's local cache increases for a longer time period.
7. Conclusion

We design a continuous query processing framework for range and k-nearest-neighbor queries in mobile peer-to-peer (P2P) environments. Our framework has two key features. Our framework provides an approximate answer for the user with two personalized QoS guarantees, namely, coverage and accuracy.

The user is able to collaborate with peers to maintain query answers. Our framework has four main control flows. The user derives an answer from the local cache and measures the quality of the answer. If the answer satisfies the user's QoS requirements, it is returned to the user. Otherwise, the user enlists neighbors for help to turn in their cached information to refine the answer. If the refined answer still cannot satisfy the user's QoS requirements, the user searches the required search area of the query to get the answer. Then the user collaborates with peers to maintain the answer. We evaluate our framework through experiments.

The results show that our framework is efficient and scalable in terms of communication overhead, and the QoS requirements achieve a performance tradeoff between the communication overhead and the quality of query answers.
