Abstract: We report a case of sinonasal paraganglioma presenting with episodes of epistaxis. A 55 year old male presented with a nasal mass. It is an uncommon site of presentation and in an uncommon age group. A high grade of suspicion is required to diagnose sino nasal paraganglioma. However, CT Scan and histopathology helps in early diagnosis and treatment. Surgical excision done with cranialization of frontal sinus with fascia lata graft, followed up for 1 year without any evidence of disease recurrence.

Keywords: Sinonasal; Paraganglioma; Fascia Lata.

1. Introduction

Rarely paraganglioma have been described in areas like the sinonasal tract where there is apparently no paraganglionic tissue and very few cases of definite paraganglioma arising primarily in the nose or paranasal sinuses have been reported, presenting with nasal obstruction, profuse epistaxis and facial swelling. Complete excision of the paraganglioma is normally curative. We report a case of nasal paraganglioma and discuss the diagnosis and therapy. Malignant transformation of benign paraganglioma is rare and transformation of paragangliomas to other types of malignancies is even rarer.

2. Case Report

A 55 year old man presented in emergency hours in the department of otorhinolaryngology, silchar medical college & hospital, silchar with history of massive bleeding from nose for last 3 days and a swelling at the root of nose for last 4 months. There had been several episodes of mild intermittent nasal bleeding. There was no complain of nasal obstruction but hyposmia. Immediately anterior nasal pack was given and 1 unit of whole blood was transfused.

Figure 1: Preoperative photo of sinonasal paraganglioma.

2.1. On gross examination, a smooth, firm, non tender, nonpulsatile, diffuse swelling about 4X5 cm size in its greatest dimensions extending from root of nose over its dorsum. The overlying skin was normal with no local rise of temperature.

2.2. ENT examination on anterior rhinoscopy revealed a mass at the roof of the nose bilaterally involving the septum with shift towards right. Nasal endoscopy suggested mass arising from the septum & roof of the nose in the 2nd pass bilaterally.

Figure 3: Nasal endoscopy (2nd pass) showing mass in the left nostril arising from the roof & septum of nose.

2.3. Eye examination: Visual acuity, ocular motility was within normal limits, eye lid, conjunctiva, cornea, iris, anterior chamber, lens & pupil of both eye was normal. Fundoscopy was insignificant. Hemoglobin was 8.6gm%, while other laboratory tests were within normal limits. Blood pressure during the pre-operative hospital stay was 150/90 mm Hg (supine position, Left arm).

2.4. Radiological imaging: CECT PNS showed an enhancing expansile soft tissue density mass is noted involving the frontal sinus, bilateral ethmoid sinus, anterosuperior nasal cavity & extending up to subcutaneous plane causing bulging of subcutaneous plane. The mass was causing erosion & remodeling of anterior & posterior walls of frontal sinus, erosion of ethmoidal septae & nasal septum is also noted. Erosion of right lamina papyracea & cribriform plate is noted causing asymmetry of ethmoidal roof. The mass is extending into anterior cranial fossa. Extension into medial & superior aspect of right orbit is also noted.

Figure 3: Nasal endoscopy (2nd pass) showing mass in the left nostril arising from the roof & septum of nose.

3. Operative Details

Under all aseptic & antiseptic conditions general anaesthesia was given. Lumbar drainage catheter was put in l3-l4 space in order to prevent post operative rise of intracranial tension.

Bicoronal flap was raised & tumour was assessed & removed along with surrounding mucosa. Posterior wall of frontal sinus was also removed & tumor was found to be restricted in extradural space. Dura was intact. Estimated blood loss intraoperatively was around 1500ml intraoperatively patient was transfused with 3 units of whole blood & 2000ml of crystalloids.

Cranialization of frontal sinus was done with lattismus dorsi flap. No intraoperative or postoperative complications were found. Lumbar drainage catheter removed after 48 hours when nasal pack was removed after confirming no elevations in the intracranial pressure over 2 days & no CSF leakage.

4. Histopathology Report

A histopathological finding shows it to be a paraganglioma.

5. Discussion

Paraganglionic chemoreceptor cells of neural crest origin give rise to benign, slow growing but locally invasive tumour known as paraganglioma [1].

Almost half of these occur in the temporal bone, arising from either the cochlear promontory (i.e. typanicum) or the jugular blub (i.e. jugulare), nearly 1/3rd in the carotid body, nearly 1/8th in the region of the high cervical vagus and the rest at various sites of the head and neck[2]. The most common site of occurrence being adrenal glands. In the head and neck area, common sites of occurrence are the carotid body, orbit, larynx, and the nasopharynx, but paragangliomas are rare in the nasal cavity and paranasal sinus.

In the nasal cavity, the middle turbinate, lateral nasal wall and superior nasal vault are the most common sites. In paranasal sinuses, the ethmoid sinus is the most common site of occurrence [4, 5, 6]. Nearly 10 percent of paragangliomas are malignant [7].

In approximately 10 percent of patients, tumours are multifocal and up to 5 percent of tumours secrete catecholamines. [3]

Common symptoms include recurrent epistaxis, nasal obstruction and frontal headache. The clinical presentation depends on the localisation of the tumour. In this case, the patient presented with epistaxis, facial swelling & hyposmia. Hyposmia is probably due to mechanical obstruction by the lesion.

They may also be associated with some syndromes such as multiple endocrine neoplasia type 2b (MEN IIb), von Hippel–Lindau disease, neurofibromatosis types I [8]. In this case, we did not have any syndromic involvement. It is estimated that about 10–50% of paraganglioma cases are familial (autosomal dominant) [1]. The genes for the familial paraganglioma have been recently identified at the 11q23 locus [9]. Also, 4–19% of all head and neck paragangliomas have been reported to be malignant [10].

The presence of metastasis is the only definite criteria for malignancy as there are no reliable histopathological criteria to distinguish between benign and malignant paragangliomas [1,11] and since the lesions are almost impossible to remove completely, postoperative radiotherapy is then mandatory [3].

In our case, we could not demonstrate any evidence of metastasis to the regional nodes or distant organs. He has been followed up for 12 months, and no additional symptoms or signs indicating recurrence have been identified.

6. Conclusion

Rarely, are the paragangliomas of the sinonasal region reported in the literature. Benign paraganglioma, may occasionally, both clinically and radiologically resemble malignant sinonasal tumour so a high grade of clinical suspicion is required to diagnose such a rare & curable tumor. It may be provisionally diagnosed in any patient with nasal mass associated with severe epistaxis. To conclude, histopathology is the spine for definitive diagnosis.
