Literature Survey on Various Outdoor Propagation Model for Fixed Wireless Network

Chandan Kumar Jha, Reshu Jain

Abstract: The main focus of this review paper is to encompass the earlier and recent advances in popular propagation model for wireless communication channel. The paper covers the wide area of radio communication in a subtle and elastic manner. The advantages and disadvantages of the existing propagation models have also been discussed.

Keywords: Path-loss, Path-Loss Models, Attenuation

1. Introduction

For the proper designing of a cellular network, it is very important to determine the parameters such as coverage area, frequency assignment, SNR and C/I ratio. These parameters are determined by conducting a series of propagation measurements, which are expensive and time consuming. It is therefore important to develop an effective radio propagation model for cellular network. [1] Radio propagation models can be classified into Indoor propagation model and Outdoor Propagation model

2. Review of Propagation Model

Different outdoor models deployed in radio propagation [2] are
Empirical Model
Deterministic Model
Stochastic Model

2.1 Empirical Models

An empirical model is simply based on observed and measured data alone. It can be further classified in to two sub heads, time-dispersive and non-time-dispersive. The SUI (Stanford University Interim) model is one of the perfect examples of time-dispersive models. The models like COST-231 Hata model, Hata and ITU-R model are examples of non-time dispersive models.

2.2 Deterministic Models

These kinds of models deploy laws of electromagnetic wave propagation for determination of received signal strength in a definite region of concern. And as the modern times are the times of site-specific propagation studies, these can be deployed both for outdoor & indoor scenarios in deterministic form. Here actual 3-D designs of buildings or concerned environment like foliage equivalent to some dielectric slab etc. are made based on some database. There after ray tracing techniques are used to associate representation with the software being used, representing fundamental phenomenon of reflection, diffraction and scattering. It is more of computerized form of comparative analysis and is becoming increasingly important with advent of high-speed computational technologies coming in.

2.3 Stochastic Models

Stochastic models are used in terms of random variables being deployed for representation of some or the other factors influencing the behavioural nature of radio waves in action. These models have a concern of correctness and accuracy. These are mostly used for prediction at and above 1.8 GHz.

3. Models for Path Loss

3.1 Free Space Path Model

In this model, the received power is a function of transmitted power, antenna gain and distance between the transmitter and the receiver. The basic idea is that the received power decreases as the square of the distance between the transmitter and the receiver subjected to the assumption that there is one single path between the transmitter and the receiver. The received signal power in a free space at a distance ‘d’ from the transmitter is [2], [8]

\[ P_R = P_T G_T G_R \left( \frac{\lambda}{4\pi d} \right)^2 \] (1)

where,
- \( P_T \) - Transmitted signal power
- \( P_R \) - Received signal power
- \( G_T \) - Transmitter antenna Gain
- \( G_R \) - Receiver Antenna Gain
- \( \lambda \) - is the wavelength

It is common to select \( G_T = G_R = 1 \)

\[ P_T \quad P_R = \left( \frac{4\pi d}{\lambda} \right)^2 = \left( \frac{4\pi f}{c} \right)^2 \] (2)

Expressed in dB as

\[ L(\text{dB}) = 10 \log \left( \frac{P_T}{P_R} \right) \]
\[ = 10 \log \left( \frac{4\pi d}{\lambda} \right)^2 \]
\[ = 20 \log \left( \frac{4\pi f}{c} \right) \]
\[ = 32.44 + 20 \log d + 20 \log f \] (3)

From the above equation, we can clearly see that as the frequency or the distance is doubled, the path loss increases by 6dB

### Figure 1: Path Loss Graph for table 1

#### 3.2 Two Ray Ground Model

The two ray ground reflection model is based on geometric optics and considers both direct path and the ground reflected propagation path between transmitter and the receiver. This model has been found to be reasonably accurate for predicting the large scale signal strength over the distance of several kilometres. The received power at a distance ‘d’ from the transmitter for the two ray ground model has been expressed as [2]

\[
P_R = P_T G_T G_R \left( \frac{h_T h_R}{d^2} \right)^2 \quad (4)
\]

when expressed in dB:

\[
L (dB) = 40 \log d - (10 \log G_T + 10 \log G_R + 20 \log h_T + 20 \log h_R) \quad (5)
\]

#### 3.2 Okumura Model

The model developed by a Japanese radio scientist, Okumura, as a part of extensive measurement campaign conducted in 1968, is one of the most widely used models for propagation in urban areas [4]. This model is applicable for frequency range from 150 MHz to 1920 MHz. The median path loss in urban area is given by

\[
L_{50} (dB) = L_f + A_{\mu} - G(h_t) - G(h_R) - G_{Area} \quad (6)
\]

where,

- \(L_f\) is the free space propagation loss
- \(A_{\mu}\) is the medium attenuation relative to the free space
- \(G(h_t)\) is the base station antenna height gain factor
- \(G(h_R)\) is the mobile station antenna height gain factor
- \(G_{Area}\) is the gain due to the environment

The values of \(G(h_t)\) and \(G(h_R)\) can be determined as

\[
G (h_t) = 20 \log \left( \frac{h_t}{200} \right) \quad (7)
\]

\[
G (h_R) = 10 \log \left( \frac{h_R}{3} \right) \quad (8)
\]

The major disadvantages of this model are the slow response to the rapid changes in the terrain. Hence the model gives good result in urban and sub-urban region but is not good in rural areas. Common standard deviation between the predicted and the measured path loss values are around 10 dB to 40 dB.

#### 3.3 Hata Model

The Hata Model is the empirical formulation of the graphical path loss data provided by the Okumura. This model is applicable from 150 MHz to 1500 MHz [5]. The median path loss in urban area is given by

\[
L_{50} (urban) = 69.55 + 26.16 \log f - 13.82 \log h_t - a(h_r) + (44.9 - 6.55 h_t) \log d \quad (10)
\]

where,

- \(f\) is the frequency in MHz
- \(h_t\) is the effective base station antenna height ranging from 30m to 200m
- \(h_R\) is the effective mobile antenna height ranging from 1m to 10m
- \(d\) is the separation between transmitter and the receiver in km
- \(a(h_r)\) is the correction factor for effective mobile antenna height

For small to medium size city \(a(h_r)\) in dB is given by [3] [5]:

\[
a(h_r) = (1.1 \log f + 0.7) h_r - (1.56 \log f + 0.8) \quad (11)
\]

and for a large city \(a(h_r)\) in dB given by:

\[
a(h_r) = 8.29 (\log(1.54 h_r)^2 - 1.1; f \leq 300 MHz \quad (12)
\]

\[
a(h_r) = 3.2 (\log(11.75 h_r)^2 - 4.97; f \geq 300 MHz \quad (13)
\]

In order to obtain the path loss in open rural areas, the modified formula is:

\[
L_{50} (dB) = L_{50} (urban) - 4.78 (\log d)^2 + 18.33 \log f - 40.94 \quad (14)
\]

The following table shows the path loss using Hata model using following set of parameters in urban areas

3.4 Cost 231 Hata Model/PCS extension to Hata Model

Hata model is applicable till the max. frequency range of 1500 MHz[1] and hence cannot be used for GSM 1800 or for systems operating at frequency range above 1500 MHz. The extension of the frequency range is achieved by the COST 231 Hata model. Cost 231 Hata model is usable in the frequency range of 1500 MHz to 2000 MHz.

The formula for the median path loss is given by:

\[ L_{50(urban)} = 46.3 + 33.9 \log f_c - 13.82 \log h_t - a(hr) + (44.9 - 6.55 \log h_t) \log d + C_m \] (15)

Where,
- \( d \) is the distance between transmitter and the receiver in km
- \( f \) is the frequency in MHz
- \( h_t \) and \( h_r \) is the effective height of the transmitting and receiving antenna in m
- Parameters \( C_m \) is defined as 0dB for sub-urban and rural environment and 3dB for urban environment.

For small and medium sized city, \( a(hr) \) in dB is given as

\[ a(hr) = \begin{cases} 
1.1 \log f_c - 0.7 & \text{if } f_c \leq 300 \text{ MHz} \\
1.16 \log f_c - 0.8 & \text{if } f_c > 300 \text{ MHz} 
\end{cases} \] (16)

\[ a(hr) = \begin{cases} 
8.29(\log 1.54h_t)^2 - 11 & \text{if } f_c \leq 300 \text{ MHz} \\
3.2(\log 11.75h_t)^2 - 4.97 & \text{if } f_c > 300 \text{ MHz} 
\end{cases} \] (17)

Cost-231 Hata Model is restricted to the following range of parameters
- \( f \): 500MHz to 2000 MHz
- \( h_t \): 30m to 200m
- \( h_r \): 1m to 10m
- \( d \): 1Km to 20 Km

The following table shows the path loss using COST 231 Hata model using following set of parameters in urban areas:
- Base Station Antenna ht.30m
- Mobile station Antenna ht.2m
- Transmitting Frequency: 1800 MHz

3.5 Stanford University Interim(SUI) model

SUI model was proposed by IEEE 802.16 wireless group of frequency range below 11GHz. This is basically the extension of Hata Model with frequency band greater than 1900 MHz. The correction factor in SUI model is its terrain based classification along with the foliage distribution. The path loss expression for the SUI along with its correction factor is

\[ L = A + 10Y \log \left( \frac{d}{d_0} \right) + X_f + X_h + e \text{ for } d > d_0 \] (19)

where,
- \( d \): distance between transmitter and receiver antenna
- \( d_0 \): 100
- \( \lambda \) is the wavelength
- \( X_f \) is the correction factor for frequency>2GHz
- \( X_h \) is the correction factor for receiving antenna height
- \( e \) is the correction factor for shadowing effect
- \( Y \) is the path loss component

The factor ‘e’ is log normally distributed and accounts for the shadowing due to foliage and other similar hindrances. The typical value of ‘e’ lies between 8.2 to 10.6 dB.

3.6 Walfisch and Bertoni Model

This semi-deterministic model was developed by Walfisch and Bertoni and considers the impact of roof-top and building heights by using diffraction to predict average signal strength at the street level[6][12]. This model considers the total path-loss to be the product of three factors i.e

\[ S = L_0 \times Q^2 \times L_{rts} \] (20)

where,
- \( L_0 \) is the free space path loss between isotropic antennas
- \( L_{rts} \) is based on the diffraction and determines the signal loss from the roof-top to the street
- \( Q^2 \) reflects the reduction in the signal power due to hindrances from the building blocks

3.7 Walfisch and Ikegami Model

This model utilizes the Walfisch Bertoni model [12] and comprises of the three terms[9]

\[ L_{b} = L_0 + L_{ts} + L_{msd} \text{ for } L_{rts} \geq L_{msd} > 0 \] (21)

\[ L_{b} = L_0 \text{ for } L_{rts} > L_{msd} > 0 \] (22)

where,
- \( L_0 \) is the free space path loss
\( L_{\text{msd}} \) is roof to street diffraction loss
\( L_{\text{roof}} \) is multi-screen diffraction loss

The roof to street diffraction and scatter loss is given as

\[
L_{\text{msd}} = -16.9 \cdot 10 \log (W) + 10 \log f + 20 \log \Delta h_{\text{mobile}} + L_{\text{orr}} \tag{23}
\]

where,

\[
\Delta h_{\text{mobile}} = (h_{\text{roof}} - h_{\text{mobile}})
\]

the difference between the height of the building on which the base station is located \( h_{\text{roof}} \) and the height of the mobile antenna \( h_{\text{mobile}} \).

\[
L_{\text{orr}} = \begin{cases} 
-10 + 0.3549 \theta & 0 \leq \theta \leq 35 \\
2.5 + 0.075(\theta - 35) & 35 \leq \theta \leq 55 \\
4.0 - 0.114(\theta - 55) & 55 \leq \theta \leq 90 \\
\end{cases}
\]

\( \theta \) is the angle of incidence relative to the direction of the street.

\[
L_{\text{msd}} = L_{\text{bsb}} + K_a \log d + K_f \log f - 9 \log b \tag{25}
\]

where,

\( b \) is the distance between the building along the signal path.

\( L_{\text{bsb}} \) and \( K_f \) represents the increase of the path loss due to reduction of the base station antenna height.

\[
\Delta h_{\text{base}} = h_{\text{base}} - h_{\text{roof}}
\]

Recently modification to Cost-231 Walfisch Ikegami model has been reported which takes into account multiple reflections due to building blocks [13]

### 3.8 Ericsson 9999 model

This model was developed by Ericsson engineers and permits modification of the parameters according to the propagation environment [10].

Path loss for this model is given by

\[
L = a_0 + a_1 \log d + a_2 \log h + a_3 (\log (11.75 h))^2 + g(f) \quad \text{(26)}
\]

and \( g(f) = 44.49 \log f - 4.78 (\log f)^2 \quad \text{(27)} \)

Parameters \( a_0, a_1, a_2 \) and \( a_3 \) are constants having the default values of \( a_0 = 36.2, a_1 = 30.2, a_2 = 0.1 \) and \( a_3 = -12 \).

### 3.9 Lee Model

W.C.Y. Lee proposed this model in 1982. This model consists of two parts. The first part is an area to area prediction which is used to predict path loss over a general flat terrain but does not account for a particular terrain. But this area to area to prediction is not adequate for hilly terrain. The second part of the Lee Model uses area to area prediction model as the base and then develops a point to point model. The point to point prediction considers whether LOS conditions exist or not. In case the LOS exists, the path loss slope is given as

\[
P_o = P_{\text{to}} \left( \frac{r}{r_0} \right)^{-\gamma} \left( \frac{f}{f_0} \right)^{-\alpha_0} \tag{28}
\]

Where,

\( P_o \) is the signal power (in watts) at a distance of \( r \) from the transmitter.

\( P_{\text{to}} \) is the signal power (at the point of interception) at a distance of \( r_0 \) from the transmitter.

\( f \) is the signal frequency.

\( f_0 \) is the reference signal frequency.

\( \alpha_0 \) is the adjustment factor for the antenna height transmitter power and antenna gains

\( \gamma \) is the path loss slope

### 4. Conclusion

The survey of the important model discussed gives a clear insight into the fact that for an analysis to be drawn out regarding the specific model with respect to any data set, the median values of the path-loss is calculated which is specific to the kind of environment, terrain and other such factors.
