Abstract: Data aggregation method in a wireless sensor network (WSN) is used for sending local representative data to the sink node which is based on the spatial correlation of sampled data. The problem occurs in recent spatial correlation models in sensor node’s data are not appropriate for measuring the correlation in a complex environment. The representative data are inaccurate when compared with real data. The data density with correlation degree is necessary to resolve the problem. The spatial correlation is measured that measures the correlation between a sensor node’s data and its neighboring sensor node’s data. The data aggregation is necessary for minimizing power utilization during the data transmission in wireless sensor network and multilevel network clustering method is used for reducing power consumption. Based on a data density correlation degree (DDCD) clustering method representative data.

Keywords: Data aggregation, clustering methods, energy efficiency, wireless sensor network.

1. Introduction

Wireless sensor network (WSN) is a collection of devoted autonomous sensor nodes that observed physical or environmental conditions differently, such as pollution levels, humidity, temperature, sound, wind direction, pressure, etc. To cooperatively deliver data through the network to a main destination. WSNs were initially designed to facilitate military applications such as battlefield surveillance; but its usages have since been drastically extended to monitoring machinaries, industrial processes, health, and controls. The WSN consist of "nodes" which may be differ in numbers from a few to several hundreds or even thousands, where every node is in connection with at least one sensor (or sometimes several). The sensor node is equipped with a tiny processor, a small battery, a radio transceiver antenna, and situate of transducers that used to gather information. They describe the variations in the environment of the sensor node [3]. Topology for WSNs can vary from a simple star or mesh network to an advanced multi-hop wireless mesh network.

The propagation of data takes place between the hops of the network with the help of routing or flooding techniques. To attain high energy saving and long network lifetime, nodes can grouped into clusters and can be arranged in a hierarchical manner. In the working process Clustering algorithm includes partitioning of sensor nodes into several clusters, and each cluster selects one sensor node as cluster-head (CH) [2]. In clustered sensor networks, the nodes do not transmit their collected data to the sink or base station (BS), but to designated cluster heads (CH) which aggregate the data packets and send directly or via multi-hop communication to the BS [3], [11]. In-network data aggregation reduces the amount of data transmission and communication; hence the energy consumed, especially in large WSNs. The main idea is to combine partial results at intermediate nodes during data transmission. [1].

2. Literature Survey

In [4], Genetically derived and secured cluster based data aggregation (GDSDA) in WSN the CHs are chosen by considering the node connectivity, which interns act as a DAG. The genetic algorithm is used for cluster based data aggregation. When the cluster member wants to transmit data to the aggregator, a data encryption technique is utilized. The confidentiality to the data packet (DP) is offered by crypto module (CyM), thus ensuring the authenticity and integrity of the sensed data.

In [5], Tiny Aggregation (TAG), a generic aggregation service for ad hoc networks of Tiny OS motes. They classify aggregates according to four properties that are particularly
important to sensor networks. The first is duplicate sensitivity. Duplicate sensitive aggregates will change when a duplicate reading is reported while duplicate insensitive aggregates are unaffected by duplicate readings from a single device. Second, excellent aggregates return one or more representative values from the set of all values; summarized aggregates compute some property over all values. Third, monotonic aggregates have the property that when two partial state records, \(s_1\) and \(s_2\), are combined via \(f\), the resulting state record \(s'\) will be greater or smaller than obtained in cluster-based data aggregation networks produced by the DDCD clustering method. Also, the amount of data conveyed to the sink node can be minimized. The WSN is modelled by undirected graph \(G = (V, E)\). Where \(V\) is the sensor node set consisting of all sensor nodes in the WSN, \(E\) is the edge set consisting of all links in the WSN. The antenna of sensor node \(I (I \in V)\) aim an omnidirectional antenna, with a communication radius of \(\alpha (i)\). In cluster-based data aggregation networks, the data transmission process is that every cluster head sends aggregated data obtained from its member nodes to the sink node by one hop or multi-hops.

3. Analysis

Papers are reviewed and analyzed related to clustering and aggregation mechanisms in WSN. Those techniques are reviewed, are different from each other, some are based on density of deployed sensor nodes, while some are based on node connectivity, energy, position, etc. In TAG approach, the most of the significant computation time is utilized for data aggregation purpose. Also the number of messages to be exchange is high. Data aggregation is performed on the information present in the database in the form of queries. This extends time complexity.

In GDSDA, the CHs are chosen based on the node connectivity, then the genetic algorithm is used. When the cluster member wants to transmit data to the aggregator, a data encryption technique is utilized. Here nodes connectivity does not guarantee the largest possible energy node will be elected as cluster head and hence may lead to node exhaustion.

KCMRM selects CHs based on high mobility and high initial energy. However, evaluating high mobility is expensive than finding immobility in WSN. This algorithm focuses on removing empty clusters. In node ranking approach, nodes are ranked by calculating the distance, the current energy level of nodes and scheming the number of rounds that they can be clustered heads for. This algorithm highly enhances the network lifetime by choosing highest energy node.

In DDCD clustering method, clusters are formed based on their level of correlation, the sensor nodes having high correlation are distributed in the same cluster. This allows aggregated data to be obtained more accurately.

4. Conclusion and Future Work

The comparison of various clustering and aggregation techniques have been done and presented in this paper. The direct further work on the DDCD clustering method is developing a method which could confirm the parameters adapted to the real sampled data, especially the data threshold has major effect on clustering performance. In the data transmitting process, the energy of sensor nodes should be considered to construct an energy balanced networks. Hence, this will be researched in our future work as well. Based on the analyzed parameters, data density correlation degree and node ranking algorithms are energy efficient for immobile nodes in Wireless Sensor Network. Implementing data
density correlation degree, clustering and electing a cluster head based on node rank would increase the network lifetime.
