Abstract: *Introduction:* Candida species are the most common cause of fungal infections worldwide. Candida species are the fourth leading cause of health care associated infections and the third most common cause of central line-associated bloodstream infections. Candida species are associated with the highest overall crude mortality of all nosocomial bloodstream infections comparable to that of *Pseudomonas* and exceeding that of *Staphylococcus aureus* infections. The vast majority of invasive *Candida* infections are caused by only four species which include *C. albicans*, *C. glabrata*, *C. parapsilosis* and *C. tropicalis*. Identification can be done by conventional method as well as by using chromogenic media. *Aim:* To isolate and identify the various candida species from clinical samples by both conventional and chromogenic method. *Material methods:* Various samples received in laboratory from patients of all age group and both sexes with suspected *Candida* infection were included in this study and the positive isolates were identified by conventional as well as chromogenic method. *Results:* Total 121 isolates of candida species were found of which 21-40 years was the most common age group and both sexes with suspected *Candida* infection were included in this study and the positive isolates were identified by conventional as well as chromogenic method. *Conclusion:* Candida albicans is the main cause of candidiasis; however, non-albicans *Candida* species such as *C. glabrata*, *C. tropicalis* and *C. parapsilosis* are now frequently identified as human pathogens. Species identification using Hicrome *Candida* agar is rapid, technically simple, easy but for early identification of *C. glabrata* and *C. parapsilosis* both the corn meal agar and Hicrome *Candida* agar should be used.

Keywords: Candida species, Hicrome candida agar.

1. Introduction

*Candida* species are the most common cause of fungal infections worldwide, the fourth leading cause of health care associated infections and the third most common cause of central line-associated bloodstream infections. They are associated with the highest overall crude mortality of all nosocomial bloodstream infections comparable to that of *Pseudomonas* and exceeding that of *Staphylococcus aureus* infections. The genus is composed of a heterogeneous group of organisms and more than 17 different *Candida* species are known to be the aetiological agents of human infection. Among species of *Candida*, *C. albicans* is most often associated with serious fungal infections. Other *Candida* species also have emerged as clinically important opportunistic pathogens. The vast majority of invasive *Candida* infections are caused by only four species which include *C. albicans*, *C. glabrata*, *C. parapsilosis* and *C. tropicalis*. The clinical manifestations of disease are extremely varied, ranging from acute, subacute and chronic to episodic. Involvement may be localized to the mouth, throat, skin, scalp, vagina, fingers, nails, bronchi, lungs, gastrointestinal tract or become systemic as in septicaemia, endocarditis and meningitis. Identification of yeast pathogens by traditional methods like growth pattern on cornmeal agar, carbohydrate fermentation test, carbohydrate assimilation test are labour intensive and requires several days and specific mycological media. Chromogenic media contain chromogenic substrates which react with enzymes secreted by target microorganisms to yield colonies of varying colours.

2. Material and Methods

After approval from institutional ethical committee, present prospective study was conducted in tertiary care hospital. Various samples received in laboratory from patients of all age group and both sexes with suspected *Candida* infection were included in this study. Informed consent was taken from patients for sample collection. Clinical details were noted in the case record form. Patients who were on antifungal treatment were excluded. The specimens for laboratory investigation were collected from the clinically suspected cases of candidiasis under strict aseptic precautions. The various clinical specimens collected were oral swabs, ear swabs, vaginal swabs, urine, stool, CSF, sputum, blood, pus, nail scrapings etc. Two swabs/specimens were taken from each case. The specimens were transported immediately to the laboratory taking care not to dry out the specimens. One of the specimens was subjected for direct examination and the other for the culture. All the above samples were subjected to various mycological tests.

1) **Direct examination by KOH Mount**
2) **Gram stain**
3) **Culture on SDA(at 25°C and 37°C)**
4) **Growth on blood agar**
5) **Germ tube test for speciation:** A small portion of an isolate colony of the yeast to be tested was suspended in a test tube containing 0.5 ml human serum. The test tube was incubated at 35°C for 2 hours. A drop of yeast–serum suspension was placed on a microscopic slide, overlaid with a coverslip and examined microscopically for varying swelling of pneumococcal colonies at 24 hours.
presence of germ tubes. **Observation:** Filamentous extension from yeast cell with no constriction at the neck was considered as germ tube.

6) **Growth pattern on CMA for speciation:** Isolated colonies of Candida were picked up with inoculating wire. Three parallel cuts 1 cm apart were made into the surface of Cornmeal-Tween agar, holding the inoculating wire at about a 45-degree angle. A sterile coverslip was laid on the surface of agar, covering a portion of the inoculated streaks. The inoculated plates were incubated at 30°C for 24-72 hours in a closed moisturized chamber. At the end of incubation period plates were examined microscopically (under 10x and 40x) at the edge of coverslip and the pattern of growth was observed to make a presumptive identification.

7) **Carbohydrate assimilation test:** Yeast nitrogen base medium was melted in a boiling water bath and allowed to cool to up to 47-48°C. Yeast suspension was made from a 24-48 hours old culture in 4 ml of distilled water. The turbidity of suspension was adjusted to match no. 5 McFarland standards. The yeast suspension was poured in to molten yeast nitrogen base agar. It was mixed thoroughly by inverting bottles several times. Yeast–agar mixture was poured in to sterile Petri dish and allowed to solidify at room temperature. Carbohydrate discs purchased from HiMedia, Mumbai were evenly spaced on the plate. Inoculated plates were incubated at 25°C and examined by indirect light every other day for 14 days. Any amount of growth around a disc was considered as yeast assimilated that carbohydrate. Species were identified based on pattern of carbohydrate assimilation.

8) **Growth on chrome agar:** Isolated species were inoculated on HiCrome Candida differential agar to improve species identification based on coloured colony morphology. These agar plates were incubated at 37°C for 48 hours. The species were identified by characteristic colony colour as per HiMedia technical data M1297 A

- **C. albicans** - Light green coloured smooth colonies
- **C. tropicalis** - Blue to metallic blue coloured raised colonies
- **C. glabrata** - Cream to white smooth colonies
- **C. krusei** - Purple fuzzy colonies

Total number of Candida species isolated was 121. Out of 121 isolates, **Candida albicans** (51.24%) was the most common species. Among NAC, **C. tropicalis** (23.97%) was most common followed by **C. glabrata** (10.74%), **C. krusei** (7.44%), **C. parapsilosis** (4.13%) and **C. dubliniensis** (2.48%).

### 3. Observation and Results

In present study, 121 isolates of *Candida species* were found. Species identification was done by both conventional method and Hicrome Candida differential agar.

In our study conventional method was considered as reference method for speciation. It included of germ tube formation, growth pattern on Cornmeal-Tween agar and carbohydrate assimilation test. Approximately 7 to 14 days were required for species identification using these methods. However some species were presumptively identified using conventional method within 72 hours, while using Hicrome Candida agar species were identified within 48 hours. All species were correctly identified by Hicrome Candida agar as C. glabrata.

We obtained 100% sensitivity and specificity of HiCrome Candida differential agar for C. albicans, C. tropicalis, C. krusei and C. dubliniensis but sensitivity and specificity of Hicrome Candida differential agar for C. glabrata was 100% and 95.37% respectively.

4. Discussion

The incidence of infections caused by Candida species has increased considerably over the past three decades, mainly due to the rise of the AIDS epidemic, an increasingly aged population, higher numbers of immunocompromised patients and the more widespread use of indwelling medical devices. Candida albicans is the main cause of candidiasis; however, non-albicans Candida species such as C. glabrata, C. tropicalis and C. parapsilosis are now frequently identified as human pathogens.6

Total 121 Candida species were isolated from various clinical samples. In present study, most of the Candida isolates (39.67%) were predominant in the age group of 21-40 years (figure 1) which correlates with study conducted by DharwadS et al7 and Jaggi T et al.8

We found female preponderance in our study (figure 2) which was concordant with the study conducted by Sajjan AC et al9 and Dharwad S et al.7 This is supported by higher percentage of vaginal swab sample included in our study.

Among the various clinical isolates of Candida species we obtained C. albicans (51.24%) as the most common isolate followed by C. tropicalis (23.97%), C. glabrata (10.74%), C. krusei (7.44%), C. parapsilosis (4.13%) and C. dubliniensis (2.48%) (Table1). While non-albicans Candida were 48.76% (figure 3). In respect to predominance
of *C. albicans* isolates and distribution of species, similar results were found in study conducted by Pfaffer MA et al., 16 Saidjan AC et al10 and Mondal S et al. 11

Factors like increased use of antifungal drugs, use of broad spectrum antibiotics, long term use of catheters and increase in the number of immunocompromised patients contributes to the emergence of non-albicans Candida species. 12

Among non-albicans Candida we found *C. tropicalis* as a most common isolate which was concordant with study conducted by Xessi I et al13, Shivprakash Sa et al14 and Pethani JD et al. 15 Higher isolation of *C. tropicalis* may be because of its endogenous transmission and also as it is considered to develop systemic infection in 50-60% of colonised patients. 16 Considering the predisposing factor in association with *Candida* infection, a study done by Arora D et al 17 found intra venous catheter as most common risk factor followed by prolonged antibiotic and immunosuppression. Also study conducted by Saidjan AC et al 18 found diabetes as most common risk factor followed by pregnancy and drug intake. While in our study (figure6), we found antibiotic usage (14.88%) as most common risk factor followed by diabetes (13.22%).

For differentiation among different species of *Candida* conventionally germ tube test, growth pattern on corn meal agar and sugar assimilation tests are being used which are technically difficult, time consuming and difficult to interpret which may take 72 hours to two weeks for species identification. 18, 19 Chromogenic agar is technically simple, easy to interpret and rapid method to differentiate among different *Candida* species. It facilitates the detection and identification of *Candida* species and provides result in 24-48 hours. Among the newer tests; chromogenic agar is rapid and cost effective as compared to other expensive systems like API systems, Vitrek 2 ID system and molecular methods. 20

We obtained 100% sensitivity and specificity of HiCrome Candida differential agar for *C. albicans, C. tropicalis, C.krusei* and *C. dubliniensis* but sensitivity and specificity of HiCrome Candida differential agar for *C. glabrata* was 100% and 95.37% respectively (table 5). However our study correlates with following studies showing high sensitivity and specificity of chromogenic agar.

</table>

For *C. glabrata*, specificity of HiCrome Candida agar was 95.37%, as 5 species of *C.parapsilosis* (identified by conventional method) were identified by HiCrome Candida agar as *C. glabrata*. Shettar SK et al. 24 reported that on HiCrome Candida agar *C.parapsilosis* gave same cream colour as that of *C.glabrata*. Ghelardi E et al 25 studied Chromogenic Candida agar (CCA, Oxoid, basingtoke, UK) for identification of *Candida* species. According to their study, this medium didn’t allow discrimination of *C. glabrata* and *C.parapsilosis*.

This may be because of *C. glabrata*, *C. kefyr*, *C. parapsilosis* and *C.lusitaniae* appear as a variety of beige/brown/yellow colours due to the mixture of natural pigmentation and some alkaline phosphatase activity. *C.glabrata* and *C.parapsilosis* can be easily differentiated from growth pattern on Cornmeal agar as *C. glabrata* doesn’t produce pseudohyphae. Thus, the combination of Cornmeal agar and HiCrome Candida agar can be used for early identification of *C. glabrata*. 24

**Conclusion**

Although our study showed *C. albicans* as most common species causing candidial infection, non-albicans Candida are rising among various clinical samples. Species identification using HiCrome Candida agar is rapid, technically simple, easy to interpret as compared to the time consuming, technically demanding and difficult to interpret conventional methods. HiCrome Candida differential agar can be reliably used for identification for *C. albicans, C. kruise, C. tropicalis*, and *C. dubliniensis* but for early identification of *C. glabrata* and *C. parapsilosis* both the corn meal agar and HiCrome Candida agar should be used. To avoid simultaneous use of cornmeal agar and HiCrome Candida agar, we recommend HiCrome Candida agar to be improved further to differentiate other non-albicans Candida species.
