Abstract: Myocardial ischaemia reperfusion is associated with activation of intracellular death proteases known as calpains. Isolated rat heart was subjected to 30 min ischaemia followed by reperfusion for 120min. The effect of calpain inhibitor calpastatin in induced myocardial injury assessed in terms of infract size measured macroscopically, release of LDH and CK have been investigated. Agarose gel electrophoresis was used to assess the DNA fragmentation. TUNEL staining was done to investigate the apoptotic index. Calpastatin has attenuated ischaemia reperfusion induced increase in LDH,CK, myocardial infarct size ,DNA smearing and apoptotic index. It may be concluded that inhibition of intracellular death proteases prevented ischaemia reperfusion induced myocardial cell injury in terms of apoptosis and necrosis.

Keywords: Calpain, Calpastatin , Myocardial injury, Mitochondrial damage, Rat heart

1. Introduction

Apoptosis may lead to necrotic cell death [1]-[4]. The transition from reversible to irreversible injury is characterized by the development of a severe membrane permeability defects that allows the unregulated influx of divalent and trivalent cations including calcium[5]. Reperfusion is associated with rise in calcium [6] which leads to activation of calpain-a calcium dependent membrane protease implicated in necrotic cell death [6] and is involved in signal transduction of apoptosis [7].

Tissue damage in ischaemic areas involves both apoptosis and necrosis and calpain participate in both the processes [8]. Reperfusion leads to rise in calcium level which causes calpain—a calcium dependent protease activation, implicated in damage of myocardial structural proteins leading to membrane break down and eventually cell death [9]. Reperfusion results in sodium ion influx followed by Ca2+ accumulation which may activate calpain and consequently produce cleavage of associated proteins. The cleaved activated fragments acts on mitochondria causing its dysfunction and release of pro-apoptotic factors resulting in DNA fragmentation and cell death. On the other hand release of cytochrome –c produces depletion of ATP stores [6] and lead to necrotic cell death [10]. The transition from reversible to irreversible injury is characterized by the development of severe membrane permeability defects [5],[11] and degradation of membranous proteins [12]. The mode of cell death shifts from apoptotic to necrotic due to use of ATP stores by apoptosis[2]. Therefore, apoptosis may lead to necrotic cell death [1]-[4].

During ischaemia and reperfusion, calpain activity is increased through both an increase in the expression of calpains and a decrease in the expression of its endogenous inhibitor- Calpastatin [13]. Calpastatin suppresses conformational changes in calpain molecule during the initial stages of its activation and inhibits binding to its cell membrane and degradation of membrane proteins [12],[14]. The selective inhibition of calpain activity by calpastatin [15] has improved function of heart which were declined as a result of ishaemia and reperfusion.

2. Materials and Methods

2.1 Drugs

Calpastatin (Calbiochem, CA, USA), Proteinase K(Sigma-Aldrich, St. Louis, USA) and RNAse(Hi Media, Mumbai, India) were used to carry out the study.

2.2 Animals

Wistar albino rats of either sex were used to carry out studies. Rats were heparinised and sacrificed by stunning; heart rapidly excised and immediately mounted on Langendorff’s apparatus [16].The preparation was perfused with Krebs-Heinslet (K-H) solution pH 7.4, maintained at 37°C and bubbled with 95% O2 and 5% CO2. Coronary flow rate was maintained 6-9 ml/min and perfusion pressure was kept constant at 70mm Hg. Global ischaemia was produced for 30 min by closing the inflow of physiological solution and it was followed by reperfusion for 120 min. Two thin electrodes fixed at ventricular apex and origin of aorta were employed to record ECG(BPL, MK 801, Banglore, India) for monitoring heart rate.

2.3 Infarct size Measurement

Infarct size was measured and expressed as percentage of total left ventricular volume (%LVV) and left ventricular weight (%LVW) respectively by Volume and Weight method. [17],[18].

2.4 DNA extraction and Gel electrophoresis

It was carried out for measuring the extent of necrosis of myocardium [19]. The concentration of DNA was determined spectrophotometrically at 260nm. Protein contamination of DNA was accessed by determining the
ratio of absorbance at 260nm and 280nm which should not be more than 1.75. To detect the internucleosomal cleavage, 10-12 µg of extracted DNA was added to equal volume of loading dye and it was loaded in the well. Electrophoresis was carried out using 1.8% agarose gel in 1X TBE buffer for 1.5 hrs at 400mA and 3W in submargine electrophoresis unit(Pharmacia Biotech, Freibury, Germany). Ethidium bromide was added to gel for DNA detection.

**TUNEL Staining**

TUNEL positive cardiomyocytes were counted and apoptotic index was calculated using the formula (1) [20].

\[
\text{Apopotic Index} = \frac{\text{Number of TUNEL positive cell nuclei}}{\text{Number of total cell nuclei}} \times 100
\]

**Estimation of LDH**

LDH was estimated in coronary effluent by 2,4-DNPH method [21] spectrophotometrically at 440nm.

Optical density of Test (O.D.\(_T\)) and control (O.D.\(_C\)) was measured against distilled water.

\[
\text{Net optical density of test} = O.D.\(_T\) - O.D.\(_C\) \quad (2)
\]

Enzyme activity was calculated from standard plot by making O.D.\(_T\) on Y-axis and extrapolating it to corresponding enzyme activity on X-axis.

**Estimation of CK**

CK was estimated in coronary effluent and Optical density of test (O.D.\(_T\)), standard(O.D.\(_S\)) and blank(O.D.\(_B\)) was measured spectrophotometrically against distilled water at 520nm [22].

\[
\text{CK} = \frac{O.D.\(_T\) \times \text{Creatinine taken} \times \text{Incubation time} \times \text{coronary effluent}}{O.D.\(_S\) - O.D.\(_B\)} \quad (3)
\]

The protocol has been designed to evaluate the effects of peptide calpain inhibitor Calpastatin on ischaemia-reperfusion induced myocardial injury (Fig. 1).

**3. Results and Discussion**

The present study describes the changes in terms of lactate dehydrogenase (LDH) and creatine kinase (CK). Maximum increase in the release of LDH is noted either immediately or 30 min after reperfusion. The noted release of LDH immediately after reperfusion may be due to sustained ischaemia and late spurt in the release of LDH noted after 30 min of reperfusion may be as a result of reperfusion. Peak increase in the release of creatine kinase (CK) after 5 minutes of reperfusion is used as a measure of lethal cardiomyocyte injury. Apoptosis generate high molecular weight fragments which cannot be detected by agarose gel electrophoresis. TUNEL (terminal deoxynucleotidyltransferase mediated UTP nick end labeling) technique has been employed to determine the apoptotic cell death (Fig.1 sham control). Myocardial ischaemia and reperfusion is associated with the activation of calpains which consequently produce apoptotic cell death through release of proapoptotic factors. That’s why perhaps global ischaemia for 30 min followed by reperfusion for 120 min has significantly increased apoptotic index estimated by TUNEL staining (Fig.2-Fig.5).

Calpain is specifically inhibited by calpastatin which is a peptide inhibitor. It suppresses the conformational changes in the calpain structure necessary during the initial stages of its activation and binding to the cellular membranes and consequent degradation of membrane proteins. The mechanism underlying the reperfusion induced necrotic cell death involves onset of mitochondrial permeability transition (MPT). Opening of permeability transition pores in mitochondria causes release of cytochrome c along with depletion of ATP and ultimately leads to necrotic (energetic)
cell death. Hence global ischaemia for 30 min followed by reperfusion for 120 min has significantly increased necrotic cell death measured in terms of infarct size and release of LDH and CK. The specific inhibition of calpain activity by calpastatin may be responsible for the noted decrease in apoptotic index (Fig.6), infarct size (Fig.7) and release of CK (Fig.8) and LDH (Fig.9).

Figure 6: Effect of Calpastatin on Apoptotic Index

Figure 7: Effect of Calpastatin on infarct size

Figure 8: Effect of Calpastatin on CK release

Figure 9: Effect of Calpastatin on LDH release

The mode of cell death shifts from apoptotic to necrotic because of use of ATP during apoptosis and consequent depletion of ATP store. Therefore atypical pattern of DNA fragmentation occurred which likely represent a smear formation. Apoptosis and necrosis are reported to coexist in acute ischaemia and reperfusion. Thus it is possible to suggest that DNA smearing noted in present study may reflect apoptosis induced necrotic cell death. The specific inhibition of calpain activity by calpastatin (20nM and 30nM) ultimately block apoptosis induced necrotic cell death may be responsible for the noted decrease in DNA smear formation. The noted inhibition of calpain activity by Calpastatin may be because of its peptide nature and consequent better membrane permeability and availability in the cytoplasm.

4. Conclusion

On the basis of results obtained in the present study, it may be concluded that

1) Isolated rat heart subjected to ischaemia of 30 min followed by reperfusion for 120 min produced significant increase in myocardial injury measured in terms of infarct size and release of LDH and CK. It produced marked increase in apoptotic index and DNA smearing. It suggests that ischaemia and reperfusion has produced apoptotic and apoptosis induced necrotic cell death in isolated rat heart.

2) The peptide inhibitor of calpain - calpastatin significantly decreased ischaemia-reperfusion-induced apoptotic index and attenuated ischaemia and reperfusion induced apoptotic cell death.

3) The peptide inhibitor calpastatin (20nM and 30nM) have prevented ischaemia-reperfusion-induced increase in ventricular DNA smearing, which has occurred as a result of apoptotic-induced-necrotic cell death.

4) The peptide inhibitor calpastatin (20nM and 30nM) significantly attenuated ischaemia-reperfusion-induced increase in myocardial infarct size and release of LDH and CK. These results suggests that ischaemia and reperfusion induced necrotic injury has been prevented by calpastatin.

5) The compound calpastatin is effective to attenuate ischaemia-reperfusion-induced increase in apoptotic index, DNA smearing and myocardial injury. It may be due to the peptide nature of calpastatin and its better membrane permeability.

6) The proposed hypothesis (Fig.10) supports the above salient findings and shows the site of action of calpastatin to attenuate ischaemia –reperfusion induced myocardial cell death.
