Abstract: The predominant disease in the oral cavity and pharynx is cancer which forms a major oncology concern in India constituting about 30% of all the malignancies due to the high prevalence of tobacco chewing in the form of Gutka, Khani or Mawa, tobacco quid (Paan) or Areca nut in India. Squamous cell carcinoma accounts for 90% of cases of malignancy to affect this region. The development of modern cross section imaging techniques i.e. CT and MRI has substantially altered the treatment and management of malignancies of oral cavity. ANA staging accuracy of clinical examination with endoscopy was only 58%, but it was increased significantly when combined either with CT (accuracy 80%) or with MR imaging (accuracy 85%). These cross-sectional imaging techniques are also important for localization of potential biopsy sites in patients with occult primary and helped the surgeon in taking biopsy from the exact site instead of taking random multiple biopsies on a clinical assessment. Other imaging modalities like color Doppler and PET have also contributed to head and neck imaging especially in evaluation of nodal status.

Keyword: Oral cancer, MDCT, MRI, Oropharynx

1. Introduction

Imaging of the oral cavity, oropharynx and hypopharynx, which comprises the upper portion of the aerodigestive tract has always been a challenge to general radiologist. These three regions are distinguished from each other because pathologic processes differ in their presentations, prognosis and histological grades.

The oral and pharyngeal cancer forms a major oncology concern in India constituting about 30% of all the malignancies due to the high prevalence of tobacco chewing in the form of Gutka, Khani or Mawa, betel tobacco quid (Paan) or Areca nut or Paan (without tobacco). Squamous cell carcinoma accounts for 90% of cases of malignancy to affect this region.1

Tumor volume and lymph node infiltration are important factors that influence the therapeutic approach and the prognosis of the patient with SCC. Direct laryngoscopy is most accurate in evaluating the mucosal surface of the aerodigestive tract. In fact, such examinations frequently identify superficial carcinomas that cannot be detected on MRI or CT. Submucosal extension cannot be sufficiently assessed by endoscopy and physical examination but can be evaluated with MRI or CT. Clinical examination alone frequently underestimates the extent of disease.

Pretherapeutic staging of the tumors of the oropharynx, hypopharynx, the oral cavity and floor of mouth is important and should be thorough and exact to ensure appropriate therapy. Particularly important is the assessment of infiltration of deeper compartments and the topographic relationship of the tumor to vascular structures.

Cross-sectional imaging techniques like multidetector spiral CT scan and MRI have significantly altered the treatment and management of the oral cavity and oropharyngeal and hypopharyngeal lesions and are considered as modalities of choice for assessing this complex region. Their main advantages reside in their capacity to show at best the normal anatomy and exact extent of low lying tumours. CT Scan outlines most lesions satisfactorily especially after administration of contrast material with good temporal and spatial resolution, is optimal for defining bone destruction and identification of metastatic lymphadenopathy.

Axial images with a slice thickness of 5 mm are advocated in various imaging protocols, although MDCT technology is capable of acquiring high-resolution (submillimeter) studies of the whole neck in less than 20 seconds. When overlapping images are reconstructed from raw data with a nominal slice thickness of 0.5–1.25 mm, multiplanar reformation (MPR) images of the tumor can be viewed interactively in arbitrarily chosen imaging planes. The price for this is a significant increase in reconstruction and data transfer time and storage demands. In addition, hundreds of images to review can diminish the productivity of a radiologist.

On the other hand MRI provides excellent tumour contrast with good delineation of tumour margins and early detection of bone marrow invasion with considerable fewer artifacts from bone and dental amalgams. In current publications...
however there are no definite guiding principles whether MDCT or MRI should be used as a primary imaging modality for oral cavity and oropharyngeal carcinomas.

Oral cancer being the 3rd most common type which accounts for over 30% of all cancers in the country. Relatively the mean age of occurrence is around 55 years, in the adult population. Incidence in the pediatric population is comparatively <0.25%. Younger individuals are the susceptible sector of the society, with an undue exposure of risk factors such as tobacco. 2/3rd of the oral cancer is prevalent in males whereas there is much variation in females. Effect of ageing and regional differences are associated with disease-specific risk factors, that attribute to the variation in incidence and pattern of the disease. Over 5 people in India die every hour everyday because of oral cancer and the same number of people die from cancer in oropharynx and hypo pharynx. CANCER registration is not compulsory in India, so the true incidence and mortality may be higher, as many cases are unrecorded and losses follow up. Most commonly the disease involves patients in the 5th through 7th decades of life. Men are afflicted 3 to 5 times as frequently as females. Smoking, tobacco and alcohol abuse constitute the most significant risk factors.

**Oral Cavity** consists of multiple sites/regions and includes lip, alveolar ridges, hard palate, retro-molar trigone, floor of mouth, anterior 2/3 of the tongue and buccal mucosa.

**Oropharynx** is that portion of pharynx, which extends from the anterior tonsillar pillar inferiorly to the pharyngoepiglottic folds and superiorly to the soft palate. It includes base of the tongue, the tonsil, the tonsillar fossa, the soft palate and the posterior pharyngeal wall.

**Hypopharynx** begins as the continuation of the oropharynx at the pharyngoepiglottic fold superiorly, and extends inferiorly to the inferior aspect of the cricoid cartilage, where it continues as the cervical oesophagus. Hypopharyngeal cancers are often named for their location, including pyriform sinus, posterior pharyngeal wall, or posteri orcoid pharynx. Most of the hypopharyngeal carcinomas arise in the pyriform sinus. In India, 65-85% of hypopharyngeal carcinomas involve the pyriform sinuses, 10-20% involves the posterior pharyngeal wall, and 5-15% involve the postericoid area.

**Aim**

To compare and correlate CT staging of oral, oropharyngeal, hypopharyngeal malignancies with clinical staging.

**Objective**

1) To study the contribution of CT in providing additional information about the lesions.
2) To assess the extent of local, regional spread, depth of invasion and extent of lymphadenopathy for staging and treatment planning in advanced oral and pharyngeal malignancy.
3) To study and record osseous involvement.

2. **Material & Method**

2.1 Study Design:

A Prospective study conducted between June 2014 - Jan 2016, suspected of having oral and pharyngeal malignancies, in the Department of Radio-diagnosis, Krishna hospital, Krishna institute of Medical sciences, Karad were included in this study.

2.2 Sample Size:

After assessment of exclusion & inclusion criteria total 70 patients suspected of having oral and pharyngeal malignancies were included in the study provided the clinical diagnosis was confirmed on histopathological examination.

2.3 The Following Were Excluded From The Study:

1) Patients who have received some form of therapy (RT/CCT/Surgery).
2) Patient's allergic to iodinated contrast media.
3) Metastases in the region of interest due to primary elsewhere.
4) Un-cooperative or very sick patients.

Patient's names, age, gender, dietary habits, life style, presenting symptoms and signs were recorded as per the proforma. Each patient was subjected to a clinical examination including neck palpation, direct /indirect laryngoscopy, fiberoptic/rigid endoscopy and clinical staging was there by obtained. Thereafter, the patient underwent baseline computed tomographic examination of the relevant area.

3. **Scanning Protocol**

The computed tomography examination was performed on Siemens Emotion 16 MDCT with tube voltage, 120 kV; effective tube current, 150 mAs; collimation, 0.75 mm; table feed, 12 mm/rotation; and rotation time, 0.5 second. The effective radiation dose for a typical scanning range of 250 mm was 3.6 mSv for men & 4.1 mSv for women.

The patient lies supine on gantry table and was instructed against swallowing, moving or talking during scanning. Contiguous 5 mm sections will be obtained from canthomeatal line to the thoracic inlet. 5mm sections were retro reconstructed in 1.5 mm axial, coronal and Sagittal planes.

The axial sections were taken parallel the body of the mandible.

In cases of extensive primary lesion the sections were extended till the superior or inferior limit of the lesion. The CT study was carried out after administration of bolus of 100 ml of non ionizing iodinated contrast media (Omnipaque) administered intravenously at the rate of 3ml/second, after obtaining pre-contrast sections in the region of interest. Two phases were obtained; Arterial phase
at 25 seconds and Delayed phase at 180 sec from the time of administration of contrast.

For the purpose of staging, the staging schemes in common use currently (viz. TNM primary tumor staging, AJCC nodal staging, clinical classification of nodes, etc.) were followed in each case.

**Radiological Criteria for Lymph Nodes Metastasis:**
1. Minimal axial diameter of 1 cm (in short axis)
2. Central Necrosis
3. Irregular ill-defined outline
4. Conglomeration of lymph nodes

**Criteria Used for Extra Nodal Extension:**
1. Intranodal tumor - well circumscribed mass with a distinct interface between it and surrounding fat.
2. Extranodal tumor - ill-defined staining margin without clear distinction between it and surrounding fat. Evidence of edema of thickening of surrounding fibro-adipose tissue or muscles.

**TNM Classification of primary tumor for carcinoma of the Oropharynx, oral cavity (including lip):**

**Annexure C**

Nodal Classification

**Perineural Extension of the Tumor Was Defined As:**
1. Enlargement of neural foramen.
2. Thickening or abnormal enhancement of the nerve.
3. Abnormal soft tissue density in relation to the nerve, not contiguous with the primary lesion.
4. Atrophy of the muscles supplied by the nerve.

Interpretation of images was done without detached prior information of the results of clinical examination and the malignancy was staged independently (according to the guidelines mentioned in the AJCC Manual for Staging of Cancer, Edge SB, Byrd DR, Compton CC, et al., eds.: AJCC Cancer Staging Manual. 7th ed. New York, NY: Springer, 2010).

4. Observation & Result

Out of seventy cases of oral cavity, oropharyngeal and hypopharyngeal malignancies included in this study 34 cases (49%) were from oral cavity, 16 cases (23%) were from oropharynx and 20 cases (28%) from hypopharynx. These cases were further categorized according to the subsites and M/F ratio.

Of the total no. of cases maximum no. of cases were seen in 4th and 5th decade i.e. 72%. About 22% of cases were seen above 60 years of age. And only 6% cases below 40 years.

42% of patients presented with oral or neck mass. About 30% of cases had a pre-existing oral ulcer and in 10% cases there was a history of leukoplakia.

88% of the cases studied had a history of tobacco use commonly in term of bidi or cigarette. However, chewing pan & Gutkha was also common. 20% of patients had history of long-term alcohol abuse. Only 10% patients had no history of tobacco or alcohol abuse of which most were females.

### Chart 1: T staging according to primary site as evaluated by Clinical staging

- Most of the primary malignant lesions evaluated clinically in our study for oral cavity were T2 lesions (38.2%). However on CT most cases were stage T4 (50%).
- In 15/34 cases (44.1%) the T-stage of CT correlated well with clinical stage.
- In 14/34 cases (41.1%) the T-stage was upgrade by CT stage as compared to clinical evaluation.
- 4 cases (11.7%) two each of hard palate and anterior tongue were graded as NA on CT Scan because of the superficial ulcerative nature of the lesions. CT could only diagnosis some thickening of hard palate in these cases even on coronal scanning.
- Another case of carcinoma of floor of mouth was under staged by CT even on coronal scan because of superficial ulcerative nature of the lesions.
- Significant additional information was however provided by CT in the above 5 cases of oral cavity that was important during surgery.

### Chart 2: T staging according to primary site as evaluated by CT staging

5. Discussion

This study conducted in the Department of Radio-Diagnosis, Krishna Hospital, Karad included 70 new cases of oral cavity and pharynx.

Sex Distribution

The distribution of cases according to the sex was 60 males and 10 females, constituting the sex ratio of 6:1. Men are more commonly affected than females.

Age Distribution

Our study also demonstrated that 65% of cases were in the age group of 40 to 60 years, in accordance to observations made by Notaniet al. Hospital Cancer Registry. About 22% of cases were seen above 60 years of age. And only 6% of cases below 40 years of age.

Risk Factors

In our study 88% cases gave a history of the use of tobacco in one of its forms, bidi, cigarette, pan, gutkha etc. Another 24% patients had a history of alcohol intake, which is known for its synergistic effect in the cancer causation. These findings corresponded to the data published by Notaniet al., who reported a 90% attributable risk of oropharyngeal tumors associated with the use of tobacco in one of its forms. Desai et al. also stressed on the role of tobacco in causation of the malignant lesions in oral cavity.

Distribution of Malignancies According to the Primary Site

Most of the cases in our study were of oral cavity (49%); Oropharynx (23%) and (28%) were of oropharynx. Our data corresponded to the cumulative data published by the National Cancer Registry Programme, and the Delhi Cancer Registry. In oral cavity maximum no of cases were of Buccal mucosa. Tonsil and base of tongue constituted most of the cases of oropharynx and Pyriform fossa in hypopharynx which correlated with the data Vincent Devita et al.

12/20 cases (60%) correlated with N-stage of clinical examination. Central Necrosis was seen in 8 cases.
Classification of Oropharyngeal Malignancies by Histological Type
In our series 92.5% cases were of squamous cell carcinoma. 5% cases were adenocystic carcinoma of minor salivary glands. And only 2.5% cases were of NHL. The above percentage correlated well with V. Devita et al.\textsuperscript{10}

Stage Distribution
Most of the tumor (70%) in this study were advanced lesion as evaluated by CT in T3 and T4 stages at the time of presentation to our institution, probably secondary to the hospital bias related to the delay in the patient presentation to a tertiary institution like our hospital.

A large number of studies are available comparing the CT findings of the extra-cranial head and neck malignancies with histopathological findings. However, only a few of these compare the CT findings with the clinical findings.

Easy accessibility of this region to the clinical inspection and palpation allows for a thorough clinical assessment of the tumors. Therefore, the majority of cases diagnosed in this area were correctly staged by clinical examination in our study - 19/34 (55.8%) cases of oral cavity and 9/16 (56.2%) cases of oropharynx, 12/20 cases of hypopharynx (60%). The T-description of the tumor by CT and clinical examination were in correlation in 57.3% cases, CT was able to demonstrate additional findings in the rest.

Isotropic data sets can be acquired with modern MDCT scanners in a couple of seconds and MPR images can be generated in excellent quality with the help of picture archiving and communication system (PACS).

F. Aspestrand et al. in his study of 36 patients with tumor of oral cavity, pharynx and larynx concluded that a positive correlation between the CT and clinical examination was found in 53% cases. However CT was unable to define 4 primary lesions of oral cavity, two each of hard palate and Anterior two third of tongue due to superficial ulcerative nature of the lesion. In one case of floor of mouth CT could not evaluate the exact size even on coronal scanning because of large superficial component of the lesion.

CT demonstrated perineural extension in 2 cases of oral cavity by demonstrating the denervation atrophy of muscle of tongue in one case and mandible involvement in another case. This correlated well with the study conducted by Mukherji et al\textsuperscript{15} who demonstrated the CT criteria for perineural or vascular invasion by aggressive nature or the tumor margins and invasion of the sublingual space.

In 3 cases of oral cavity CT demonstrated maxillary invasion, which was diagnosed only in one case clinically thus, altering the surgical planning. Skin involvement was seen in 4 cases, where it was clinically suspected in only 2 cases. Intra cranial extension was seen in one case of tongue, in which case although primary tumor was not discernable on CT due to superficial nature of lesion but osteolytic metastasis was seen in occipital bone making the staging – M1. Erosion of pterygoid plates was seen in another 2 patients.

In malignancies of oropharynx CT upgraded the primary tumor stage in 43.7% cases and correlated with clinical T-stage in 50% cases. However only in one case of soft palate CT under estimated the true extent of the lesion due to its superficial nature.

CT was able to demonstrate the extension across the midline into base of tongue in 5 cases, of which only 2 were diagnosed clinically.

The demonstration of the pre - epiglottic fat space involvement and pterygopalatine fossa involvement in 3 cases each which did not alter the T – Stage description of tumor, where important to demonstrate as they were considered poor prognostic indicator of tumor control by radiotherapy. Schaefer et al\textsuperscript{16} concluded that CT is helpful in detection and delineation of pharyngeal tumors. In 2 cases carotid involvement was demonstrated, not suspected clinically, thus obviating the possibility of dissection of the tumor.

Thus CT is a valuable adjunct to clinical examination in T – staging as also demonstrated by Larsson et al.\textsuperscript{16} who concluded that CT is not a substitute for thorough clinical examination but adds to the information about the greater & deep extent of the lesion. These findings are also in correlation to the reports of various other authors. Murali et al.\textsuperscript{17} reported an increase in T-stage description of 33.3% cases post CT evaluation. Schaefer et al.\textsuperscript{16} reported that the CT was moderately useful in evaluation of tongue & floor of mouth lesions.

Study by Prehn et al\textsuperscript{18} showed a change clinical description in 25% of oral cavity lesions and defined the true extent of tumor infiltration in many more by CT. Larsson SG et al\textsuperscript{14} in his study concluded that normal mucosal layer of the base of the tongue often show contrast enhancement of the same magnitude as the tumor and can at times be irregular in outline because of co – existing lymphoid tissue. This superficial tumor spread can therefore be difficult to ascertain on CT but be quite obvious for the clinician.

In malignancies of hypopharynx; CT upgraded the primary tumor stage in 40% cases and correlated with clinical T-stage in 60% cases. However only in one case of posterior pharyngeal wall; CT underestimated the true extent of the lesion due to its superficial nature.

In a retrospective study comparing post-surgical pathological and CT features in 19 patients with hypopharyngeal carcinomas, Yan et al.\textsuperscript{19} reported that CT scanning has a positive predictive value of 85%, a false negative rate of 5%, and a sensitivity rate of 95%.

In another study on 60 cases of laryngeal and hypopharyngeal carcinomas, D'Souza et al.\textsuperscript{20} revealed that when compared to pathological findings, CT scanning has an advantage in diagnosing tumors invading into subglottic areas with accuracy rate of 95%, a specificity rate of 93.5%, and a positive predictive value of 82.5%.

Comparison analysis of CT scanning and pathological examinations in 21 cases of hypopharyngeal carcinoma by

Paper ID: ART20164665
Li et al found the accuracy of CT to determine carcinoma invading paraglottic space, pre-epiglottic space, fissure of epiglottis, thyroid cartilage and arytenoids cartilage is 100%, 100%, 92.3%, 77.8%, 75% and 50%, respectively. Thus, at present, CT scanning is a reliable method in studying the regional invasion of laryngeal carcinoma.

This study revealed that pyriform sinus carcinoma could easily invade fissure of epiglottis, with a positive rate of up to 98%, which was obviously related to the lateral surface of epiglottic fissure constituting the pyriform sinus. After fissure of epiglottis was invaded, tumors migrated along the surface of mucosa to reach the adjacent epiglottis, vallecula and epiglottis, therefore ipsilateral epiglottis was easier to be involved, similar to the results of Huang et al. After epiglottis was invaded, as the tumor progressed, lesions penetrated the surface of mucosa and further invaded the pre-epiglottic space (66%).

Eight cases were detected oropharyngeal side wall invasion and one case of tongue root invasion. Involvements of the oropharyngeal sidewall were caused by direct upward migration of malignancy. Involvements of the tongue root were caused by spreading from epiglottis and pre-epiglottic space. Results in this study suggest that the oropharyngeal sidewall is easier to be involved than other walls. Only one case (5%) at [4b] stage, originating from right lateral pyriform sinus, spread upwards to the soft palate after invasion to the right lateral wall in oropharynx, but the nasopharynx was not involved.

Our results were in line with those reported by Emami et al which suggests that pyriform sinus carcinoma can easily invade posterior pharyngeal wall via downward migration along the surface of mucosa, but seldom invade esophagus and upper space of lateral wall outside the pyriform sinus, epiglottis, paraglottic space, oropharyngeal sidewall, ventricular band and vocal cord, and so on, on the contralateral side. This may be because these structures are far away from the primary tumor site.

In this study, 4 cases (20%) were posterior hypopharyngeal wall carcinoma, 3 cases (75%) of which were at the advanced stage. These results suggest that posterior pharyngeal wall carcinoma are aggressive and usually invaded aryepiglottic fold anteriorly, prevertebral fascia posteriorly, esophagus inferiorly.

### Lymph Nodes

In the present study 44% cases were classified as clinically negative nodes. Post contrast enhanced CT examination, 13 of the 27 clinically negative necks (48.4%) showed evidence of nodes of more than 1 cm in size with unequivocal signs of metastasis (central necrosis, extra-capsular spread).

CT also altered the description of N-stage of 38% cases by upgrading the N-stage to N3en in 32% cases and 8% in N2c nodal stage.

This upgrading was done by demonstrating:
- Central necrosis in 30 cases
- Multiple nodes in 14 cases

### Conclusions

The findings of our study were in good correlation with those of previous authors. CT also has an impact in patient management, because detection of occult metastasis to regional nodes, contra lateral side, as well as extra capsular spread is poor prognostic. Predicator and alter the patients management. Extracapsular spread when present rules out a radical neck dissection in such patients for regional control of disease.

Eight cases were detected oropharyngeal side wall invasion and one case of tongue root invasion. Involvements of the oropharyngeal sidewall were caused by direct upward migration of malignancy. Involvements of the tongue root were caused by spreading from epiglottis and pre-epiglottic space. Results in this study suggest that the oropharyngeal sidewall is easier to be involved than other walls. ### Conclusions

The findings of our study were in good correlation with those of previous authors. CT also has an impact in patient management, because detection of occult metastasis to regional nodes, contra lateral side, as well as extra capsular spread is poor prognostic. Predicator and alter the patients management. Extracapsular spread when present rules out a radical neck dissection in cases, where it is planned for regional tumor control.

6. Conclusions

Imaging is essential in the management of oral cancers. It augments clinical findings to plan appropriate therapy. MDCT allows rapid scanning and fast acquisition of data helping in reconstruction and generation of excellent quality multiplanner images. MDCT helps in categorization of malignant lesions of the oral cavity and pharynx according to the TNM classification by demonstrating greater extent of tumor through various means. MDCT accurately demonstrates osseous and cartilaginous involvement and determines resectability, helps to plan the precise extent of resection, and indicate whether organ conservation therapy should be offered.

Thus routine use of MDCT is strongly recommended in all the malignancies of extra cranial head and neck region.
