Abstract: Background: The hepatitis C virus is a bloodborne virus that causes acute and chronic hepatitis infection. It is a major global healthcare problem, causing an increase level of liver-related morbidity and mortality. Up to 3% of the world’s population has been infected with the virus, equating to more than 170 million carriers of HCV worldwide. 80% of the HCV virus infected persons become persistently infected and 30% of these develop progressive liver disease such as cirrhosis and hepatocellular carcinoma (HCC), that’s why HCV infection is now the leading reason for liver transplantation. In most European countries, patients with transfusion-dependent thalassaemia and other haemoglobinopathies represent a population of patients that was infected with HCV and other infection diseases, during the years preceding the development and implementation of sensitive and specific mandatory blood screening for HCV. Methods: For this study we enrolled 103 multi-transfused patients with thalassaemia disease at the University Hospital “Mother Theresa” of Tirana, Albania. The collected blood were tested for HCV, HBV and HDV virus. Results: The prevalence of HCV virus among the thalassaemia patients was 28% (29/103). According to the age groups, we noticed that prevalence of HCV virus was higher among the patients between 10-20 years old. Meanwhile 12.6% (13/103) of the patients resulted positive for HBsAg and among them 15% (2/13) resulted positive even for HDV virus. Conclusions: Prevalence of viral hepatitis as HCV, HBV is high among the multi-transfused thalassaemia patients and is influenced by the amount of blood transfusions and the screening process of the blood donors.

Keywords: Hepatitis C Virus, Hepatitis B Virus, Hepatitis D Virus, Coinfection, Thalassaemia, Albania

1. Introduction

Hepatitis C virus (HCV) is considered the principal etiologic agent of post-transfusion hepatitis and is the main cause of chronic liver disease in multi-transfused subjects. It is a major global healthcare problem, causing an increased level of liver-related morbidity and mortality. Up to 3% of the world’s population has been infected with the virus, equating to more than 170 million carriers of HCV worldwide [1, 2, 3].

Patients with thalassaemia are at high risk of acquiring a number of viral infections during multiple blood transfusions. To prevent these infections is mandatory the screening process for antibodies anti-HCV and other viruses to the blood donors. However, it remains a challenge for our health care systems as a country that still have a high annual mortality rate, according to the data of Health Grove. Even though the annual mortality rate per 100,000 people from thalassaemias in Albania has decreased by 48.4% since 1990, it continues to be among the countries with high annual mortality rate [4].

In most European countries, patients with transfusion-dependent thalassaemia and other haemoglobinopathies, represent a population of patients that was infected with HCV during the years preceding the development and implementation of sensitive and specific mandatory blood screening for HCV, HBV and HDV, while post-transfusion hepatitis is still occurring in many countries of the developing world [5].

Even though the screening process of blood donors for HCV, the thalassaemia patients can acquire hepatitis C through the administration of HCV infected blood collected during the donor window period. For this reason the prevalence of HCV virus among thalassaemia patients is underestimated.

HCV infection, which is mainly of transfusional origin, remains a major concern in the field of thalassaemia. On average 12% – 85% of thalassaemia patients around the world including Europe are positive for anti-HCV antibodies [6, 7].

Unfortunately, there are limited data about the prevalence of HCV virus among thalassaemia patients in Albania, so this study is undertaken with the aim to represent an epidemiologic view about this infection in our country.

2. Methods

In this study, we enrolled 103 multi-transfused patients with thalassaemia disease at the University Hospital “Mother Theresa” of Tirana - Albania during 2010-2011 time frame. The collected blood samples were centrifuged and tested for antibodies anti-HCV, HBsAg and antibodies anti-HDV.

The tests were performed in the Laboratory of Blood Control for Infection Agents, at the National Blood Transfusion Centre (Tirana) using ELISA method, third generation (ABBOTT), the same method used for blood screening. Statistical analyses were done with Chi-square test. The result value of p < 0.001 were considered statistically significant for the test.

3. Results

Among 103 multitransfused thalassaemia patients, 28% (29/103) of them resulted positive for antibodies anti-HCV (Figure 1). Meanwhile, 12.6% (13/103) of the patients
resulted positive for HBsAg and from them, 15% (2/13) resulted co-infected with HDV virus.

Among the patients that resulted positive for antibodies anti-HCV, the co-infection with HBV virus was present in two cases with 6.8% (2/29). Only two patients resulted positive for HCV, HBV and HDV virus.

Prevalence of HCV virus among thalassaemia patients was 17% (5/29) at the age group <10 years old, 6.8% (2/29) at the age group of 20-30 years old and was higher for the patients belonging to the age group of 10-20 years old with 75.8% (22/29) (Figure 2). The result value of p< 0.001 were considered statistically significant for the test.

Meanwhile, the prevalence of HBV virus was 7.6% (1/13) at the age group of 20-30 years old, 30.7% (4/13) at the age group of 10-20 years old and was higher for the patients belonging to the age group <10 years old with 61.5% (8/13) (Figure 2). The result value of p< 0.279 were considered statistically significant for the test.

Since the sample size of patients who resulted positive for HDV virus is small, their distribution by age groups doesn’t have any statistical significance.

4. Discussion

Patients with thalassaemia are at high risk of acquiring a number of viral infections because of multiple blood transfusions and the need to be hospitalized more frequently. Among these infections, hepatitis B, C and human immunodeficiency virus infections are extremely important. Preventing these infections is mandatory for improving survival and quality of life of thalassaemia patients. With this study we noticed that especially the prevalence of viral HCV markers among patients with thalassaemia is higher if compared to the general population [8].

As some researches have demonstrated, due to differences in viral morphology, the viral infectivity of HCV outside an infected person endures much longer than HIV’s viral infectivity. HCV can survive outside the body, under certain conditions, increasing the risk for acquiring HCV virus [9,10,11].

It’s important to highlight the necessity of the screening process for infection diseases among the blood donors. In Albania, the law on “Blood transfusion service, control of blood and blood components” has been in force since 1995 being improved with several guidelines and regulations. In 1999 the screening tests for infection diseases have been started and in 2000 started the process of donors selection, collection, storage and transportation. In 2010, the testing for infection diseases which can be transmitted by blood transfusions, were centralised at the National Blood Transfusional Center in Tirana [12].

Because of the “window period”, even though the presence of infection is high, there’s the risk that the antibodies cannot be yet detected [13,14]. This explains in part the high prevalence of viral hepatitis among the multi-transfused patients.

Recently, HCV viremia has been routinely detected by Polymerase Chain Reaction (PCR) and it permits the detection of HCV and HBV viruses during the “window period” [15,16,17].

Due to limited financial resources available in our medical health system, the tests performed in routine for the screening process of the blood donors are only HBsAg and anti HCV serological testing.

5. Conclusions

Prevalence of viral hepatitis as HCV, HBV is higher among the multi-transfused thalassaemia patients. It depends on the number of transfusions and the screening process of the blood donors. As actually, HBsAg and anti HCV serological testing are the only routine tests used for screening the blood donors, the high risk of prevalence of viral hepatitis will be present.

6. Future Scope

Vaccination against HBV and the process of screening for the blood donors, especially with more accurate laboratory testing prior to transfusion, are of great importance for prevention of these infections among multi-transfused thalassaemia patients.
