Abstract: The most common sites of colon cancer metastasis are regional lymph nodes, liver and lungs. Axillary lymph node metastasis from colon cancer is an extremely rare clinical event being encountered in oncology practice. This scarcity of reports in English literature is therefore poses challenges in understanding its pathogenesis and thus hinders in implementation of appropriate management. We present here a case of right sided colonic carcinoma in a middle aged male patient presented with left sided axillary lymphadenopathy. FNAC showed metastatic adenocarcinomatous deposits. Following ultrasonography of abdomen and later colonoscopy guided biopsy of polyoided growth at right hepatic flexure of colon was confirmed as signet ring cell carcinoma of colon. Patient underwent palliative hemicolectomy and was offered palliative chemotherapy and was treated later with palliative radiotherapy to the painful left axillary and supracavicular swelling. He had achieved symptomatic relief from pain and tightness after radiotherapy and advised supportive and symptomatic care at home.

Keywords: colonic cancer, axillary lymphadenopathy

1. Introduction

Metastasis to locoregional lymphnodes and liver from colon cancer are a common finding in the clinical practice. Other common sites of metastasis are lungs, peritoneum and ovary. Distant sites such as axillary and supraclavicular lymphnodes are extremely rare with only four cases have been reported so far in English literature review. Here we report a middle aged man who presented to our institute with enlarged left axillary lymphnodes associated with extensive lymphedema of left arm and chest wall. He was later diagnosed as right sided colon cancer, underwent right extended hemicolectomy, received palliative chemotherapy and palliative radiotherapy and later died of disease progression.

2. Case Report

A 40 year-old male patient presented with loss of appetite, generalised weakness and frequent loose stools after food intake which was persisting since three months for which he had consulted local hospital and received symptomatic treatment and was referred to our hospital outpatient department for further evaluation and management. He was severely anaemic and received five units of packed cell transfusion before presenting to us. He had complaints of dyspnoea on exertion, dyspepsia and left sided neck and axillary swelling and tightness noticed for last one month duration which was painless and not associated with fever, cough, chest pain or hemoptysis. He was not a known diabetic, hypertensive, tuberculosis, bronchial asthma or angina and no family history of such type of illness. Fine needle aspiration cytology (NAC) from left axillary swelling was suggestive of metastatic adenocarcinomatous deposits [Figure-1] and was advised to look for the primary such as GIT, Thyroid, Lungs. Ultrasonography of abdomen showed features suggestive of carcinoma hepatic flexure of colon with metastatic lymphadenopathy. Colonoscopy revealed polyoided friable growth of about 5x4 cm lying 10 cm distal to caecum possibly in ascending colon. Colonoscopy guided biopsy revealed moderately differentiated adenocarcinoma of colon. Final diagnosis of adenocarcinoma colon with secondaries in neck and axilla which is cT3N1M1 (stage IV) was made. Patient underwent right extended hemicolectomy with ileo-transverse bypass surgery. Histopathology revealed adenocarcinoma of signet ring cell type [Figure-2] which showed alcian blue positivity for mucin [Figure-3] with tumor free proximal, distal margins, omentum and retroperitoneum. Later he received 12 cycles of palliative chemotherapy of FOLFOX. The axillary swelling was clinically found to progress in size and became tender and painful and patient was referred for palliative RT for symptomatic pain relief. Post chemotherapy follow up ultrasonography of abdomen showed normal study of abdomen. ¹⁸FDG PET-CT [18 fluoro deoxy glucose positron emission tomography] scan of whole body revealed no metabolically active disease in primary operated site. Low grade metabolically active left axillary lymphadenopathy and non FDG adiv left cervical lymphadenopathy was noted. Non FDG avid right femur and right iliac bone lesion was noted. metabolically active [soft tissue density lesion in lower chest was noted posteriorly suggestive of metastasis [Figure-4]. Patient was taken up for palliative radiation to left axillary swelling and left side neck and supraclavicular region to a dose of 39Gy in 13 fractions, 3Gy per fraction, 5 fractions per week . Patient had achieved symptomatic relief from pain and tightness following RT, with clinically significant regression of size of axillary and
In conclusion we would say that because of the dismal prognosis of such a rare clinical entity, it would always be wise to undertake a screening of these vulnerable patients for suspected colonic neoplasm in order to prevent it from progressing to an event of poor clinical outcome.
