Abstract: Diabetic nephropathy (DN) is a major micro-vascular complication in diabetes mellitus (DM). One third of type 1 DM and 1/6th of type 2 DM develop DN account for more than 30% of total end stage renal disorders (ESRD), the main cause of renal replacement therapy. It is characterized by mesangial expansion, glomerulosclerosis and increased intracellular matrix accumulation. Injury of podocytes and reduced cellular density are considered to be root of the disease. Molecular mechanisms that leads diabetic patients toward nephropathy is hyperglycemia induced production of reactive oxygen species (ROS), advanced glycation end products (AGEs), activation of polyol pathway, increased expression of TGF-β, angiotensin II and aldosterone induced oxidative injury. DN can be prevented by controlling the glycemic levels, blood pressure, body weight and consumption of low protein diets along with high potassium supplementation. Therapeutic strategies including intensive glycemic control, blockage of the renin-angiotensin system and anti-hypertensive therapies are proved to be beneficial but still failed to gain complete response. Limited researches are focused toward invent and formulate novel therapeutic agents that would be able to target at a molecular level so as to be more beneficial even if the glycemic level is not well controlled. Therapeutic strategies may include AGEs inhibitors, blockers of receptors for advanced glycation end products, PKC targeted agents, tyrosine kinase inhibitors and mitochondria targeted anti-oxidants.

Keywords: Diabetic nephropathy, ESRD, ROS, AGE, PKC

1. Introduction

DN: Characteristics and etiology

DN is the most serious secondary complication of DM with high rate of mortality which is the main cause of ESRD in adults 1. About 30% of diabetic patients develop DN 2, in the case of poor control of blood pressure and urinary albumin excretion, they lead to ESRD 3.

DN develops in following characteristic phases.

1)Elevation of kidney plasma flow and increase in GFR, hypertrophy of kidney and renal hyper-filtration
2)Renal parenchymal changes and normo-albuminuria, massengial expansion and thickening of basement membrane
3)Early hypertension and micro-albuminuria
4)Observable albuminuria
5)End stage renal disorder 4

These disorders contribute in generating of cell injury and therefore apoptosis of podocytes, extracellular proteins accumulate in tubular interstitial and in glomerular region 5.

Mechanisms of development of DN: Persistent hyperglycemia has a strong relationship with development of DN. Various mechanisms of involvement of hyperglycemia in the development of DN are proposed.

1)Activation of oxidative stress by high concentration of glucose and production of ROS
2)Production AGEs (advanced glycatated end products)
3)Activation of PKC (protein kinase C), proinflammatory transcription factor NF-κβ, transforming growth factor (TGF) and RAS (renin angiotensin system) 6.

ROS: Mechanism of production in DM and their role in development of DN

Free radical production due to hyperglycemia has important role in induction of cellular oxidative damage 7, its role in production of diabetes associated macro vascular complication is also approved. During high glucose concentration, there is overproduction of mitochondrial superoxide which is blamed to be responsible for the hyperglycemia induced apoptosis 8.

Pathways responsible for production of secondary complication of DM like AGEs formation, RAGE ligand binding, specific inhibitors of aldosase activity, activation of protein kinase C and hexose amine flux are correlated to the production of high level of superoxide induction in mitochondrial electron transport chain due to hyperglycemia 9. Superoxide converted into different other free radicals which may be more reactive and causes cellular damage by various mechanisms 10. In ETC transfer of electrons take place through complex I, II and IV which expel protons to intermembrane space thus the proton gradient generates which activates ATP synthase or complex V to bring back protons to matrix via inner membrane. In the case of higher concentration of glucose or in diabetic cells there is high level of pyruvate generated from glucose and oxidized in TCA cycle providing more NADH and FADH2 as electron donors into the ETC, increasing the voltage gradient of mitochondrial membrane till reaching of critical threshold. This is the point where complex III is blocked and become unable to transfer electrons thus electrons go back to coenzyme Q. As this coenzyme just donates one electron to molecular oxygen therefore it generates superoxide. Figure (3) The mitochondrial superoxide oxide catalyzes superoxide which yields H2O2 and O2 by other enzymes. The excivo
studies of arterial endothelial cells showed that hyperglycemic conditions increase the electron gradient up to the threshold level and thus increase the production of ROS which then can produce dynamic changes in mitochondrial morphology. The fluctuation in ROS is prevented by inhibition of mitochondrial fission11.

In diabetics patients decrease in the activity seen of GAPDH is seen where mitochondrial superoxide leads to increase the level of upstream glycolytic intermediates13.

1) Methylglyoxal generated non-enzymatically from glyceraldehyde 3P, activates AGEs pathway, increases the expression of RAGE and also activates the ligand S100 calgranuline and HMG B1
2) High level of glyceraldehyde 3P also activates PKC pathway due to production of DAG a potent physiologic activator of PKC pathway
3) Blockage of GAPDH further increases the level of fructose 6P which then undergo in hexose amine pathway and produces UDP- N acetyl glucose amine by the help of GFAT.
4) Inhibition of GAPD causes increased concentration of glucose inside the cell which is then consumed through polyol pathway by using NADPH as reducing equivalent.

Advanced glycated end products:

AGEs are the products of non-enzymatic reaction of reducing sugars and amino group of proteins, lipids and nucleic acids. AGE produced via a series of reactions in which Amadori products and Schiff bases produced prior to AGE. The production of AGEs require couple of weeks therefore glycation affects long-lived proteins for example structural components of basement membrane in which collagen is the most affecting protein but myalin, complent C3, fibrinogen, tubulin and plasminogen activator factor could be affected16,17.

In early stages of Millard reaction the rate of reaction is concentration dependent therefore the rate is improved in DM18,19. The process of glycation by glucose is slower but the rate is faster in the case of Glucose-6-P and fructose 20 the rate is accelerated by the presence of transitional metals while it is inhibited by reducing agents such as vit C 21 and green tea26.Glycoxidation is another phenomena which is used when glycation occurs along with oxidation, pentosidine and N2-[Carboxy methyl lysine] (CML) are examples of such reaction. In Millard reaction the production of dicarboxyls or oxoaldehydes is of clinical importance. These compounds produce during Amadori rearrangement as reaction intermediates. Methylglyoxal (MGO) and 3-deoxyglucose (3DG) are good examples of such intermediates27.

Methyl glyoxal with a strong electrophilic nature so it reacts with nucleophilic centers of macromolecule for example DNA, RNA and proteins therefor is considered a toxic compound in high concentrations, and can cause cell death24. It is constituted by non-oxidative mechanisms, non-enzymatically in an aerobic glycolysis, it is also produced from poly unsaturated fatty acids 25, during the fragmentation of triose phosphate, catabolism of threone and ketone bodies 26. It is related to the dihydroxy acetone phosphate an intermediate of glycolytic sequence, After detoxification it is converted to the lactate (figure)27. Furthermore, it reacts with the side chain of amino acids lysine, cysteine and arginine; it also binds with guanine base and to a lesser extends with adenine and cytosine28. It is suggested that the cytotoxic characteristic of methylglyoxal is due to its inhibitory action of DNA replication29. Mutagenic characteristic of methylglyoxal was proposed by Marnet et al.; when he observed mutagenic changes in Salmonella typhimurium cells by converting arabinose sensitive strains to arabinose resistant strains30.
3-Deoxyglucosone is another important advanced glycated end product, presence and also involvement of which is reported in diabetic microangiopathies such as retinopathy, nephropathy and neuropathy. According to the studies, the presence of 3DG is associated with the pathology and bioactivities of senile disease.

3-Deoxyglucosone forms of two distinct pathways.

1-Polyol pathway: 3-deoxy glucosone is generated after the hydrolysis of fructose 3-phosphate.

2-Maillard reactions: In this pathway first the enzymatic glycation of amino group of proteins is occurred and Amadori products are yielded and there after a multiple dehydroxylation reactions and subsequent rearrangements, the 3-Deoxyglucosone and other highly reactive carbonyl compounds are produced. 3DG is able to react with free amino group and AGEs such as pyralline and CML is generated.

By controlling the level of blood glucose with anti-hyperglycemic agents the reduction was seen in 3DG level, the level of CML was also decreased but the level of pyrallysin was not affected. Which indicate more involvement of 3DG in the production of CML rather than in pyralline.

Apart from the potential of 3-DG in producing of advanced glycation end products, it has some unique biological activities and it is accepted that the level of plasma 3DG increases in DM and also it is consider that plasma 3DG plays role in producing the complication of DM. Moreover it has been revealed that 3-DG is associated with the pathology and bioactivities of senile disease.

Accumulation of carbonyl precursor of glyoxidation product such as pentosidine and CML or dicarbonyl precursor (precursors of methylglyoxal and deoxyglucosone) and lipoxidation products are known carbonyl stress. The condition of carbonyl stress is observed in DM and uremia and it is considered as an important factor of producing and accelerating vascular damage in both conditions.

Cross linking induced by AGE

Though the AGEs are differ chemically from each other but they have some consequences of covalent cross linking of proteins. Usually stable and long lived proteins such as collagen undergo cross linking process. The main mechanism of cross linking is not fully understood but according to researchers the lysine residue of the protein is likely to be involved in. The mechanism of physiological cross linking of proteins such as collagen in which enzyme lysyl oxidase is involved, is well understood. But there is not any evidence to prove such mechanism in accelerated cross linking situation like in DM. Pathological crosslinking of proteins causes stiffness of proteins as well the process of removal by proteolytic mechanism becomes slower and thus the tissue remodeling process is also affected. All of these changes occur in aging and DM accelerates their rate. The evidence of these process are delivered by the observation of crosslinks between AGE pyralline and pentosidine by immunostaining in immunohistological studies of diabetic nephropathy and also by the correlation between accumulation of AGE and stiffness of aorta in the postmortem reports of humans.

Cross linking leads to atherosclerosis, thickening of basement membrane capillaries and sclerosis of renal glomeruli. The mechanism of developing atherosclerosis is not only by cross linking but they also trap lipoproteins and thus hampers the efflux of cholesterol from vessel walls and causes macro-vascular disease.

Interaction of AGE with their receptors:

Many receptors of AGE are known which include oligosaccharyl transferase 48(AGE-R1), Macrophage scavenger receptor type I and II, 80 K-H phosphoprotein (AGE-R2), receptor for AGE (RAGE) and galectin (AGE-R3). The receptors are present in different cells such as microglia, macrophages, podocytes, endothelial cells, monocytes, astrocytes and smooth muscle cells. In DM the expression of some receptors increased for example expression of RAGE is increased in endothelial cells of kidney. Galectine is increased in kidney of diabetic patients. The RAGE receptor which is present in endothelial cells is the well characterized, the member of immunoglobulin superfamily, multiligand in nature and plays the role of scavenger and also as a mediator of cellular signaling. According to in-vitro observation it is revealed out that when AGE-RAGE complex is produced on macrophage and microglia, it creates oxidative stress and causes activation of a free radical sensitive transcription factor NF-κB then modulates transcription factor for VCAM-1, thrombodible, tissue factor and indotheline.

As the non-enzymatic glycation in non-diabetic individual also occur but the harmful complication are mostly seen in the case of DM because for producing of complication the rate of accumulation of AGE is more important than the concentration of AGE, this was proved by comparative study of young diabetic patient with micro-vascular complication who had less concentration of AGE accumulation with older age group having more AGE accumulation but without any complication.

Activation of polyol pathway:

The first enzyme in this pathway is aldose reductase that is present in cytosol and is in monomeric form. It catalyzes the NADPH dependent reduction of glucose and other carbonyl compounds. Affinity of aldose reductase is low (high km value). So in normal glucose concentration, very small level of glucose is catalyzed by this pathway but in diabetes the intracellular glucose increases which undergo catalyzes by polyol pathway in higher rate concomitant with depletion of NADPH reservoirs. In the second step of polyol pathway fructose is produced from the oxidation of sorbitol and NADH is used as coenzyme in this reaction.

Different mechanisms are proposed to explain the harmful effects of hyperglycemic induced flux of polyol pathway include the hyper osmolarity induced by sorbitol, decrease in cellular NADPH level, decreased activity of Na+/K+...
ATPase and an increase in NADH/NAD+ ratio. As the diffusion of sorbitol across the cell membrane is not easy so it can cause osmotic damage to micro-vascular cells. Although concentration of sorbitol in diabetic cells is too low to cause damage, the other suggested mechanism is a decrease in activity of Na/K ATPase which occurs as a result of Protein Kinase C (PKc) activation. As oxidation of sorbitol increases the ratio of NADH/NAD which further causes inactivation of GADP and thus production of AGEs including DAG take place and it is previously described the latter is a potent activator of PKc. Though hyperglycemia causes increase in NADH+/NAD ratio, but the absolute concentration of NAD+ is decreased because of its utilization in the synthesis of PARP (poly ADP ribose polymerase) that is activated by ROS.

Apart from induction of abnormalities in blood flow and its permeability, PKC contributes to expression of TGF β1, type IV collagen and fibronectin in both glomeruli of diabetic rats and cultured mesangial cells. Furthermore, PKC is also responsible for fibrinolytic inhibitor PAI-1, activation of NF-κB in the regulation of membrane associated NAD (P) H dependent oxidases.

**Activation of Hexose amine pathway and its effects**

Activation of hexose amine pathway can also be contributed to the production of diabetic complications and induction of diabetic nephropathy. In this pathway fructose 6-P undergo catalysis by GFAT to provide Glucose amine 6-P a substrate for the synthesis of UDP-Glc NAc which is then utilized for the formation and synthesis of proteoglycan and O-linked glycoproteins.

HSP is considered as a part of the glycolytic pathway normally about 3% of glucose is utilized via this pathway. First step in HSP pathway is rate limiting and is catalyzed by a Glutamine:

Fructose-6Phosphate amidotransferase in result the fructose-6P and glutamine are converted to Glucose amine 6P and glutamate, subsequently GlcN-6P is metabolized to CMP-syalic acid, N-acetyl galactose amine (UDP-GalNAC) and N-acetyl glucose amine, glycolipids, essential building blocks of the glycosyl side chains of glycoproteins, gangliosides and proteoglycans. Among these metabolites, UDP-GlcNAc has attracted more interest because:

1. Its quantity is higher as compare to other metabolites of HSP
2. It regulates the entry of glucose into HSP by a feedback mechanism by binding to GFAT allosterically.
3. It plays a role of obligatory substrate for muscular and cytosolic enzyme O-Glc NAC transferase, an enzyme responsible for post translational modification of proteins by transferring of N-acetyl glucoseamine to O-linkage of serine or threonine residue of specific proteins.

GlcNAc modification has a regulatory function and usually they are found adjacent to phosphorylation site. This type of acylation have functional significance for different proteins including transcription factors c-my, Sp1, CMP responsive element binding protein, pancreatic duodenal home box-1, enzymes of cytosol and nucleus, RNA polymerase II and glycogen synthase, IRS 1 & 2 and Glu.

Studies have showed that HSP can cause insulin resistance and glucose amine that too enters HSP after the catalyzyation by GFAT also causes insulin resistance but in lower concentration. The role of HSP in the development and pathogenesis of renal and vascular complication in diabetic patients is proved by remarkable evidences. As in diabetic nephropathy the initial stage is the accumulation of extracellular matrix in glomerular region which is promoted by persistent hyperglycemia in diabetic experimental models and diabetic patients. McClain et al
suggested that in hyperglycemic conditions HSP affects vascular smooth muscles genes in smooth muscle cells. After that it become clear that for the effect of high glucose concentration, synthesis of transforming growth factor β is compulsory. Recently the mechanism of stimulation of TGF-β1 is suggested as, the sequence of promoter region of TGF-β1 homologs the glucose response elements in the gene of proteins contribute in glucose metabolism and regulated by glucose for example pyruvate kinase. GREs than by binding with stimulatory factors USF-1 and 2 enhance the expression of TFG-β1. In hyperglycemic state over expression of TGF-β1 take place which then stimulate the expression of USF-1 and 2, thus upregulate TGF-β1’s promoter activity. Apart from GRE there are two other protein binding sites in promoter region which are activated by MAP kinase and PKC, that are also dependent to a high glucose concentration.

**Glycemic control**

Hyperglycemia is considered as a major cause of development of diabetic nephropathy in both type 1 and type 2 diabetic patients. According to several research groups including the Diabetic Control and Complication Trail, intensified glycemic control can prevent the incidence and development of microalbuminuria and also overt proteinuria in type 1 diabetic patients. The 6 year study done by Okhobo et al 1995 in Japanese patient with type 2 DM, multiple insulin therapy showed marked decrease in development of diabetic nephropathy. Diabetic Control and Complication Trail (DCCT) has suggested that by controlling intensively glycemic level goal HbA1c< 6.5% and mean achieved Hb=7%) in both type 1 and type 2 diabetic patients marked reduction in the development of micro-vascular complications like retinopathy, nephropathy and neuropathy is seen. In UK, a 10 year study was done on the newly diagnosed patients with type 2 DM, in whom the intensified glycemic control, showed a 25% decrease in the rate of progression and development of secondary diabetic complications as compare to standard therapy. Study which was done by Vijan S et al 1997 showed that glycemic control in type 2 DM is more beneficial in prevention of development of secondary complications than in type 1 DM. However some controversial studies are also present like according to the research done by DCCT and Micro albuminuria study group, intensified blood glucose control was not able to decrease the rate of progression from microalbuminuria to macroalbuminuria in type 1 diabetic patients. But glycemic control along with blood pressure control in type 1 diabetic patients was reported to prevent the worsening of renal function.

In type 2 diabetic patient, the role of strict glycemic control is less studied but there are reports on some hypoglycemic agents for example Rosiglitazone is reported beneficial in decreasing the UAE rate as compare to the Glyburide. Use of metformin due to the risk of lactic acidosis is inhibited in patients with high level of creatinine in these patients use of drugs independent from renal excretion are safe, for example Repaglinide and natagliidine but sulinuria and its derivatives will worsen the condition. However in the study for type 2 patients with exogenous insulin should be administered because of low production of endogenous insulin in response to insulin secretagogues.

**Intensive blood pressure control**

Hypertension is a common problem of diabetic patients, about 40% of type 1 and 70% of type 2 diabetic patients are with normo-albuminuria thus the hypotensive agents are reported to significantly decrease the risk of development of micro and macro vascular complications. The study in UKPDs has showed that a decrease of 10mmHg (from 154 to 144 mmHg) reduces the risk of development of DN to 29%. As hypertension is consider critical to renal function so control of blood pressure with any of hypertensive agent may be beneficial but RAS blockers either ACE inhibitors or ARBs despite of their anti-hypertensive characteristics are preferred due to the role of this system in the pathogenesis of diabetic nephropathy and their effect in decreasing intraglomerular pressure that results little passage of proteins to proximal tubules.

Though the preventive effects of ACE inhibitors has not been defined yet but a 3 year study in normotensive, normo-albuminuric type 1 diabetes showed delay in progression of DN about 24% in type 2 diabetic patients and also Ramipril was reported to decrease the urinary albumin excretion rate, thus ACE inhibitors can be beneficial agents in prevention of developing DN. The meta analysis of evaluation of 12 trails containing 698 non-hypertensive type 1 diabetic patients showed ACE inhibitors are not only beneficial in decreasing the chance of progression from micro-albuminuria to macro-albuminuria but they are also beneficial in increasing the chances of regression from micro-albuminuria to normo-albuminuria. Furthermore, ARBs are proved to be efficient in prevention of the development of micro-albuminuria to macro- albuminuria in type 2 diabetic patients, treated with Irbustan 300mg/dl which showed a 70% decrease in development of diabetic nephropathy.
Novel Therapy

1. Strategies to block AGE formation: The AGE can be blocked by several pathways. Most of therapeutic strategies till now, work on the inhibition of synthesis of AGEs. Aminoguanidine is the most studied AGE blocker; it is a nucleophilic compound by interacting with the intermediates of AGEs inhibits the process of cross linking24. The studies done in diabetic animal model have shown the efficacy of aminoguanidine in the attenuation of the signal transduction, over expression of growth factor, structural and functional alteration of diabetic nephropathy75. The study done by Ateon a pharmaceutical company responsible for this research has concluded the significant reduction in the albuminuria following the administrating of aminoguanidine76. But there was no statistical significant change in GFR level. Some other AGE inhibitors that require further studies for clinical use are ALT 486, NNC 39-0028 and OPB 9195.

2. Cross link breakers: other proposed strategy of therapy is the breaking of cross linking, the idea was developed when phenacylthiazolium (PBT) a cross link breakers was discovered25. But the study conducted on diabetic rats did not prove the efficacy of PBT in the treatment of DN. Another cross link breaker is ALT 711 which is able to inhibit and also to improve age related stiffness of myocardium and has also been shown to significantly reduce blood pressure, UAE and renal lesions78, 79.

3. Receptor blocker: Shmidt and colleagues suggested another therapeutic strategy by administration of soluble, extracellular domain of RAGE (sRAGE) that was able to bind with AGE and thus inhibiting its receptor, subsequent gene activation and underlying pathophysiology80.

4. Protein kinase C inhibitors: As the number of pathogenic pathways toward DN is activated by PKc the inhibition of PKc can be efficient therapeutic strategy in the management of DN on other side there are several isoforms of enzyme performing different function, therefore while inhibiting the specific isozyme related induction of DN (PKc-β) should be targeted81. Inhibitors of PKCβ ameliorate glomerular lesions thus normalize GFR and inhibit protein excretion in diabetic rat models82. Till now the known inhibitor of PKc is LY333531 that was able to reduce UAE and GFR in diabetic rat models. That also resulted in attenuation of mesangial, reduction of collagen and expression TGF-β expression in Ren-2 diabetic rats, even in the presence of hyperglycemia.

5. Inhibition of vasopetidase: The important vasopetidases that contribute to the control of blood pressure are RAS, Kalikarin-Kinin system and natriuretic peptide system. All of these systems together play role in modulating the vascular tone, water and salt balance and have growth factor like activity. Interrelations of these systems are also important in the development of hypertension and renal complication. ACE and neutral endopetidase have structural similarities and both are zinc containing cell surface peptidases therefore can be inhibited by single inhibitor. The inhibition of both systems can lead to better control of blood pressure. Furthermore, other vasoactive peptidases are also reported to be affected by changes in these systems. For example the degradation of bradykinin is inhibited by ACE inhibitors and NEP inhibitors reduces the endothelium and potentiates the natriuretic effect of adrenomodelline (JC, 1999). Several preclinical and clinical studies are going on dual ACE/NEP vasopetidase inhibitors like Omapatriate the phase II and III studies for which are completed83. SA7060, MLD100240, MLD100173, Fasidotril, Sampatrilat, Alanojril, CGS30440 and S2140284. Number of studies are done on animal models to evaluate the comparative action of dual VPIs and ACE inhibitors. In one study the S21402 a dual VPIs was compared with ACE inhibitors and in result the S21402 was found more efficient in controlling of blood pressure while the effect on AER was similar85. The other study was done of seminephrectomized mice with some characteristics of DN, to study the effects of CGS 30440 and Omapatrilate, both of these VPIs were able to significantly reduce proteinuria86.

6. Miscellaneous therapeutic strategies: Overdose of thiamin and its derivative benfotiamin due to decrease oxidative stress, PKC and protein glycation is reported to slow the development of microalbunimuria in diabetic nephropathy86. The administration of heparin glycosaminoglycan apart from the beneficial effects of PKC inhibitors it also decreases the accumulation of tubular and glomerular matrix and inhibit the synthesis of PKC mRNA87. A medicinal second generation of AGE inhibitor and sulfoxide a glycos amin glycan also have beneficial effects in the decreasing of the urinary albumin excretion and in normalization of GFR in diabetic rats88. Taniguchi K et al 2013 suggest the role of Src kinase in collagen accumulation and PP2 by inhibition of Src kinase that leads to the inhibition of collagen IV accumulation, high glucose induced phosphorylation of proteins and the pathological mechanisms of diabetic nephropathy thus Src inhibitors were suggested as a novel therapeutic targets for diabetic nephropathy89. Role of PG in the pathogenesis and development of DN is not clear but there is higher amount of PG in the kidney of patient and also diabetic animal models with diabetic nephropathy. Makino et al 2002 showed that administration of selective antagonists of PGE receptor EP-1 subtype was able to selectively prevent development of diabetic nephropathy in STZ induced diabetic rats, Which was able to decrease massengial expansion, ameliorate glomerular hypertrophy, inhibit up regulation of fibroenectine and transcriptional growth factor β1 (TGF-β1) in mesangia cells cultured in high glucose concentration. According to this study the role of PG-EP1 system in the development of diabetic nephropathy become clear. Makino et al 2002 also explained that aspirin a non -selective prostaglandin synthase inhibitor and EP-1 antagonist both decreases mesangial expansion but aspirin is not able to inhibit glomerular hypertrophy and proteinuria while EP-1 inhibitor is able to produce these changes suggesting that the mode of action of these drugs may

DOI: 10.21275/11021802 1168
be different and suggests the nova 1 therapeutic strategy\textsuperscript{91}. Studies conducted on STZ induced diabetic rat models have suggested that in renal mitochondria high level of SO is produced along with the post transcriptional modification of mitochondrial complex III. Thus Chacko BK et al revealed out that in Ins2\textsuperscript{+/+},Akata mice targeted antioxidant therapy with mitochondria –targeted ubiquinone(Mito Q) was able to prevent and treat diabetic nephropathy\textsuperscript{95}. However the studies in human being are still needed to approve the effect of these novel drugs.

2. Conclusion

Diabetic nephropathy is a serious secondary complication of DM. That has increased the health and financial problems of diabetic patients. It is an appeal for the development of cardiovascular and major cause of renal replacement therapy. DN develops approximately after 5-10 years of the incidence of DM in 5 characteristic phases, therefore providing of quality preventive and therapeutic measures not only help in prevention of the incidence and the progression of disease but can also ameliorate the tissue damage of the kidney. For getting such a successful restorative strategies the underlying mechanism should be understood.

Persistent hyperglycemia causes to alter normal metabolism of glucose or increases the level of production of compounds which normally produce in small concentrations. High concentration of glucose and its metabolic products causes more synthesis of reactive oxygen species, activation of polyol pathway, production of AGEs, cross linking of AGEs, more expression of RAGE, activation of PKc and hexose amine pathway all of which contributes in production of oxidative stress, activation of inflammatory cytokines, inflammation and that leads to injury and damage of endothelial cells, accumulation of extracellular matrix, mesangial expansion and glomerulosclerosis, strict glycemic control, maintaining of BP at normal level, protein restricted diet, exercise and prevention of obesity are proved beneficial but maintaining of these factors are difficult and still DN is the leading cause of ESRD. Thus struggle is going on for the development of therapeutic agent which would be able to act at molecular level to prevent the incidence of DN, the propose mechanisms are AGEs blockade, cross linking breakers, RAGE blockers, mitochondrial targeted antioxidant etc. although at animal models these agents have given remarkable results but still their efficiency should be checked at humans.
