Introduction

According to the American Psychiatric Association, delirium is defined as “a disturbance of consciousness with reduced ability to focus, sustain, or shift attention, a change in cognition (memory deficit, disorientation, disordered speech) or the development of clutter perception.” Age-related changes in physiology and pharmacology can affect every aspect of perioperative care. The changes in surgical demographics will compel the anesthesiologist to become familiar with the physiology and clinical care of the aged.

Age-related diseases such as cerebral arteriosclerosis, Alzheimer’s and Parkinson’s disease are all more common with advancing age. Most strokes affect those older than 70 years and the risk doubles every 10 years after age 55. The prevalence rates for dementia and Alzheimer’s disease double approximately every five years from rates of 2 to 3 percent in the age category of 65 to 75 years to more than 30 percent in persons age 85 and older. Onset of symptoms in Parkinson’s disease usually occurs between ages 60 and 69, although in 5 percent of patients the first signs are seen prior to age 40. About 1 percent of persons age 65 and older and 2.5 percent of those older than age 80 have Parkinson’s disease.

Delirium is a very costly disorder, and health services costs associated with diagnosing, treating, and the consequences that flow from it are very high. Impairment of eyesight and hearing, certainly associated with higher incidence of this disorder. Causes of postoperative psychotic disorders are multi-factorial. Mechanisms that contribute to the postoperatively psychotic disorder (POPD) are not very well known. A lot of theories support abnormal neurotransmissions.

Increase in magnitude with advancing age, represent aging. Many theories emphasize aberrant neurotransmission. One of the most widely accepted mechanisms is cholinergic deficiency; increased serum anticholinergic activity is associated with delirium. Other hypotheses invoke abnormalities in melatonin and serotonin, with abnormal tryptophan metabolism unifying these ideas because tryptophan is a precursor to serotonin. Neuronal damage is an alternative explanation, secondary either to oxidative stress or inflammation. Proinflammatory cytokines increase in postoperative delirium, especially interleukin-6 and interleukin-8. In addition, elevations in C-reactive protein occur in delirious patients. A link between inflammation and neurotransmission has been proposed, with inflammation-induced perivascular edema leading to hypoxia and subsequent reduced synthesis of acetylcholine.

Conclusion: Post operator delirium increases the hospital financial burden, with a statistically important difference of p<0.01.
slower theta rhythm. In hypoactive delirium, hypoperfusion occurs globally in the frontal, temporal, and occipital lobes, and focally in the caudatehead, thalamus, and lenticular nuclei. Delirium improves once blood flow returns to normal, suggesting that cerebral hypoperfusion may play a role. Effects of aging on the nervous system include: selective attrition of cerebral and cerebellar cortical neurons neuron loss within certain areas of the thalamus, locus ceruleus, and basal ganglia, general reduction in neuron density, with loss of 30 percent of brain mass by age 80 decreased numbers of serotonin receptors in the cortex, reduced levels of acetylcholine and acetylcholine receptors in several regions of the brain, decreased levels of dopamine in the neostriatum and substantia nigra and reduced numbers of dopamine receptors in the neostriatum. The association of serotonergic, cholinergic and dopaminergic systems, respectively with mood, memory, and motor function, may partially account for depression, loss of memory and motor dysfunction in the elderly.

The outcomes of delirium are summarized in Figure 1. Relationships between various etiological factors in delirium. Systemic inflammation can be the result of systemic infection, trauma or surgery. Neurotransmitters with possible roles in delirium include acetylcholine, dopamine, 5-hydroxytryptamine, norepinephrine, glutamate and GABA. Phathophysiology of delirium. The evidence supports multiple mechanisms of delirium. According to the American Psychiatric Association, Delirium is defined as "a disturbance of consciousness with the reduction of the ability to focus, sustain, or change in focus, a change in the recognition (memory deficit, disorientation, spoken of unfitness) or the development of perception mess. Postoperative complications specific to elderly surgical patients such as delirium will be increasingly relevant in the coming decades. Delirium postoperative has been associated with increased morbidity and mortality and long hospital stay. With increase of the
average age the elderly surgery has increases as well. Old age is a multy factor proces where adaptive capacity is gradually reduced and gradual reducion of funcional ability of many systems is seen. With the increase of the average age the surgeries in elderly are also increased. The surgery plays an important role on emotional and spiritual deteriation on elderly. The delirium causes an increased mortality and an increasing of mental status deterioration characterized by reduction of environmental recognition as well as the disorder of alertness.

Aim of study
Is to evident the post operator delirium effects on financial burden of the hospital.

2. Material and Methods

In this study are included all patients aged over 65 years old admitted in the urology clinic, who underwent surgery. This study is prospective and random. Patients that had been diagnosed and treated for psychiatric problems (Alzheimers, Dementia senile, Scysophrenia) were excluded from the study.

All patients are evaluated preoperators for their minimental status with MMSE. Minimental examination (MMSE) is a questionnaire for the evaluation of the recognizable function. It is an easy method and valuable in trust. The highest result is 30 and a lower result 23 shows for recognition damage. Anyway it is suggested that the most significative recognition damage is with 21 points. The effectiveness of routine screening of postoperative Delirium (POD) in the elderly using Confusion Assessment Method (CAM) Psychiatrists are not necessary in this case. The number of patients was 1496.

3. Results

The patients who had post operator delirium were 270 patients, (18% of all patients). It is calculated the average day stay as well as the medicamental cost without hospital service, hotel service daily meals in cases that did not have delirium and those who did investigations.

These should be guided by the clinical presentation and are aimed at identifying an underlying cause of the delirium. Typical investigations that can be performed include:

- Full history, including collateral history and cognition testing, e.g. mini mental state examination. Full examination - look for sources of infection, including the ears and throat; look for rashes, lymphadenopathy and check for constipation.
- Bloods - include FBC, U&Es and creatinine, glucose, calcium, magnesium, LFTs, TFTs, cardiac enzymes, and PSA. Creatinine is vital to obtain an estimated glomerular filtration rate (eGFR), as this may indicate impaired renal function and affect the handling of medications, and may predispose to drug-induced delirium. Urine dipstick testing and microscopy. Blood cultures and serology, if indicated. ECG. Pulse oximetry and arterial blood gas, if indicated. Are evaluated all the data taken from patients and from their examinations as: age, usage of medications, symptoms and problems, biochemical and clinical balance, hemodynamic examination, and preoperative, intra operative and postoperative evaluations.

On the average, the patients with delirium stayed in the hospital more than the patients without delirium with a significant statistical difference between them t=5.12 p<0.01. During one year the average day stay was 8.9 days and the patients with delirium stayed on the average 9.8 days.

conscience, damaged, can rip off periferic IV, urinar catheter, sometimes even the central one. These actions have their own effect in the disease’s evolution. The factors that precipitate postoperative delirium are many, some are modifiable and some immovable. The more factors that precipitate postoperative delirium, the more evident is delirium.\cite{JAMA 1996;275:852-857}.

4. Conclusions

From this study it is evidently noticed that postoperative delirium in elderly in urology has an important influence in the increasing of the day stay in hospital than the patients who didn’t have delirium, even though they where in the same conditions, morbidity and physical status, with a statistically important difference between then. (ANOVA F=26.2 P<0.01) and certainly more cost for the hospital as well. Post operateur delirium increases the hospital financial burden, with a statistically important difference of p<0.01.

5. Recommendations

It is the duty of the anaesthesist doctor that the good management if the preoperatore, intraoperatore and post operatore period, is very important, not only in the good physical state of the elder patient, but in the psychic status as well. So it prevents the postoperatore delirium, which would bring decrease of the day stay in hospital as well the financial burden.
