Abstract: Congenital diaphragmatic hernia (CDH) usually presents in the neonatal period with respiratory distress. The presentation in adults varies from asymptomatic to unexplained symptoms, which makes CDH difficult to diagnose. We report an anesthetic management of CDH repair in an adult patient who presented with abdominal pain. CDH was an incidental finding. The patient was planned for laparoscopic CDH repair, keeping thoracotomy as alternative. Anaesthetic management was complicated by pulmonary hypoplasia on affected side, pulmonary hypertension and need of one lung ventilation. Postoperatively analgesia was also a challenge to prevent atelectasis.

Keywords: Congenital diaphragmatic hernia; pulmonary hypoplasia; thoracotomy

1. Introduction

Congenital diaphragmatic hernia (CDH) usually presents immediately after birth with severe respiratory distress, which is life threatening. Its incidence is 1:2000 - 1:5000 live births with equal gender preference [1-4]. In adults CDH presents with unexplained symptoms [5] (Table 1) and based on computed tomography in 13,138 patients the incidence [6] was found to be 0.17%.

CDH develops due to failure of the posterolateral diaphragmatic foramina to fuse properly in eighth to tenth week of foetal life. Left-sided herniation is common, as right hemidiaphragm develops earlier and the liver prevents hollow viscus from herniation [7]. For anesthesiologists CDH repair is a challenge because of high risk of aspiration, need for lung isolation to prevent over distension of lungs and facilitate good view to surgeon, a ventilation strategy and pharmacological treatment to prevent pulmonary hypertension in hypoplastic lung and post operative analgesia to prevent any further respiratory compromise.

2. Case Presentation

A 26 year old male patient (height 160cm, weight 56kg, BMI 21.8 kg/m²) presented to our emergency department with complaints of left sided upper abdominal pain and vomiting for the last one week. He had similar complaints in past also, which were managed conservatively outside and not diagnosed as CDH. There was no symptom suggestive of respiratory compromise. He had no history of any major trauma and other co morbidities. He was a cook by profession, with limited physical activity and effort tolerance was 3 - 4 METS.

On examination heart rate was 92/minute, blood pressure 120/80mm hg, respiratory rate 18/minute with no use of accessory muscle and room air saturation was 92 - 93%. Mallampatti grading was class 1. On auscultation normal vesicular breath sound were heard on right side and decreased breath sound on left side. His systemic examination showed no other abnormalities.

Complete blood count, renal profile, serum sodium, serum potassium and ECG were normal. Arterial blood gas analysis showed pH 7.4, CO₂ 24, HCO₃ 14.6, P O₂ 77, BE - 8.6, S O₂ 95.6% Chest radiography revealed absent lung marking on left side, right sided mediastinal shift, nasogastric tube coiling back to left hemithorax, and blunting of margin of left dome of diaphragm (Fig 1). CT revealed stomach, small bowel and spleen as contents of the diaphragmatic hernia. Laparoscopic surgical repair was planned keeping thoracotomy as an alternative in case of very large defect.

Comprehensive contingency plans were developed preoperatively including thoracic epidural to manage postoperative pain in case of thoracotomy and double lumen endotracheal tube (DLT) to secure airway and facilitate lung isolation. A written and informed anesthetic consent was taken with explanation focused on postoperative ICU admission and ventilation. For aspiration prophylaxis fasting of 6 hours for solid and 2 hours for liquid and premedication with injection (inj) Ranitidine 50mg intravenously (IV) and inj Metoclopramide 10mg IV one hour before surgery was given.

The right radial artery cannulation (2G, Vasofix, BBraun), one wide bore (Vasofix, 16G, BBraun) intravenous cannulation and right basilic central line (Cavafix 375, 14G, BBraun) were secured. Thoracic epidural (Perifix, 18G, BBraun) secured in T8 – T9 space. Monitoring included standard ASA monitors, temperature, invasive pressure monitoring and anesthetic agent analyzer.

Rapid sequence induction (RSI) was planned to avoid bag and mask ventilation and further airway compromise. After preoxygenation with 100% oxygen for three minutes, induction done with inj Fentanyl 100 microgm IV, Propofol 100mg IV and Succinylcholine 75mg IV. Left sided double
analgiesia managed well acidosis pulmonary hypertension in mind so 2 D ECHO could not be done should be done in mi opt lung ventilation mask ventil prophylaxis These patients are at risk of aspiration so p better to red complication. Minimal invasive surgical appr possible to prevent worsening of the condition and diagnosis is made surgery should be performed available imaging study which can detect CDH. Once treated symptomatically. Consequently many patients remain undiagnosed or just respiratory compromise, adults presents with degree of suspicion. Unlike infants who present with hypoxia, hypercarbia, acidosis and nitrous oxide were avoided. Pain should be managed well by epidural analgesia or patient controlled analgesia.

Overall anesthetic principles remain same in both infants and adults, with more careful attitude.

3. Conclusion

The diagnosis of CDH in adult is not easy and needs high degree of suspicion. Unlike infants who presents with respiratory compromise, adults presents with slight respiratory and digestive system complaints. Consequently many patients remain undiagnosed or just treated symptomatically. Chest X rays are most easily available imaging study which can detect CDH. Once diagnosis is made surgery should be performed as soon as possible to prevent worsening of the condition and complication. Minimal invasive surgical approaches are better to reduce the postoperative mortality and morbidity.

These patients are at risk of aspiration so proper aspiration prophylaxis and RSI should be planned to avoid bag and mask ventilation and further respiratory compromise. One lung ventilation should be planned for these cases for optimizing surgical conditions. The presence of a hypoplastic lung and pulmonary hypertension should be kept in mind because of late presentation and ideally 2 D ECHO should be done. We accepted the patient on emergency basis so 2 D ECHO could not be done, but keeping possibility of pulmonary hypertension in mind, hypoxia, hypercarbia, acidosis and nitrous oxide were avoided. Pain should be managed well by epidural analgesia or patient controlled analgesia.
