Testicular Feminizing Syndrome

Jayalakshmi Murupuri¹, B. Anjaiath²

Abstract: Testicular feminization syndrome is a form of pseudohermaphroditism where phenotypic female has male gonads and is genotypically male. Androgen insensitivity syndrome (AIS), also known as testicular feminization, encompasses a wide range of phenotypes that are caused by numerous different mutations in the androgen receptor gene. AIS is an X-linked recessive disorder that is classified as complete, partial based on the phenotypic presentation. The clinical findings include a female type of external genitalia, 46-XY karyotype, absence of Mullerian structures, presence of Wolffian structures to various degrees, and normal to high testosterone and gonadotropin levels. The syndrome is illustrated by a 15-year-old phenotypic female who presented with a primary amenorrhea, female-type external genitalia, an absent uterus and ovaries, and bilateral testes at the level of the internal inguinal ring. Management includes counseling, gonadectomy (bilateral orchiectomy) to prevent primary malignancy in undescended gonad, and hormone replacement. The karyotyping of family members is advocated because of known familial tendencies.

Keywords: Androgen insensitivity syndrome; Testicular feminization syndrome; Gonadectomy

1. Introduction

Intersex is a condition where person has different genotypic and phenotypic sex. In phenotypic female, it is a common cause of primary amenorrhea. Testicular feminization syndrome is a form of male pseudo-hermaphrodite, where phenotypic female has male gonads and is genotypically male. This syndrome also known as androgen insensitivity syndrome was 1st described by Morris at Yale. The phenotype is a female despite the normal male karyotyping 46 XY. The etiology of this syndrome is congenital insensitivity to androgens transmitted by means of a maternal X-linked recessive gene responsible for androgen intracellular receptors1. The incidence of androgen insensitivity syndrome is estimated to be 1:20, 000-64, 000 male births and with variable phenotype expression, this syndrome can present as complete or partial forms.

Case Report
Patient XY, aged 15 years, high school student, from lower class, came with history of primary amenorrhea.

Family History
She was last child of the three sisters. Her two elder sisters are married and having two children each.

General Examination
Phenotype female, Normal feminine looks, Height 152 cm, Weight 55 kg, Axillary and pubic hairs are sparse, Breasts not well developed (tanner 1). Smell and vision were normal. Hair line was low occipital. There was no impairment of visual fields. No thyroid swelling.

Gynaecological Examination
Labia majora, minora and clitoris were slightly ill developed. Per speculum examination revealed blind vaginal pouch, good rugosity, cervix not seen. One finger vaginal examination revealed blind vaginal pouch of approximate 3 cm, but cervix and uterus not felt. Per rectal examination confirmed these findings. Examination of inguinal region revealed bilateral swellings of about 3*4cm, firm, immobile. Her routine investigations were within normal limits. Serum gonadotropin levels (serum FSH, LH) and testosterone level were within normal limits for male. Karyotype was 46 XY. Barr body negative. She was counseled about possibility of gonadal tumor and need for the removal. She underwent bilateral orchidectomy and started on low dose estrogen therapy.

Histopathology: Microscopic appearance showed structures of both testes and both spermatogenic cords.

2. Discussion

Testicular feminization syndrome may present as complete form (CAIS) and incomplete form (PAIS). In the complete form, there is no androgen response, therefore normal external female genitalia develop and these infants are reared as females. There may be labial or inguinal swellings which contain testes. These patients most often present in late adolescence with primary amenorrhea. There is absence of uterus and ovaries on ultrasound scan or laparoscopy. Vagina is short, develops from urogenital sinus only and ends blindly. The partial or incomplete form of testicular feminization syndrome is associated with wide range of genital abnormalities and typically present at birth with genital ambiguity. Severe hypospadias associated with micropenis, bifid scrotum and bilateral cryptorchidism are common. In some patients, the external genital phenotype may be predominantly female with partial labial fusion and clitoromegaly1. Ultrasonography or laparoscopy should be done in all such patients to examine internal genital organs. Measurement of serum 17-hydroxyprogesterone and its sulphate can be done to detect testosterone biosynthetic defects². Management consist of appropriate counseling of parents regarding fertility and long term use of HRT needs to be discussed. Reconstructive surgery to external genitalia is not needed in the complete form but gonads need to be removed due to risk of malignancy. Gonadectomy should be done after puberty to prevent the risk of development of malignancy in the testes. For management of incomplete form both gonadectomy and reconstructive surgery of external genitalia is required³.
